parisons easier. Strength, porosity and permeability must be taken into account in any final rating of an admixture, but I felt that to discuss these factors at length would only divert attention from the test methods proposed, toward the admixtures themselves. The statement that admixtures "do not appreciably affect strength or permeability when used in the amount or proportion specified by the manufacturer" briefly sums up any discussion which I might make in connection with these factors.

Professor Williams discusses in his paper certain fundamental facts. He compares cement and admixtures as to the volume of paste given when equal weights are mixed to give pastes of equal flow; also, the effect on the volume of mortar under the same conditions and the effect on preventing segregation when jigged, and then proceeds to demonstrate the reasonableness of his method of study by producing a series of concretes which were alike in their tendency to segregate when made up as suggested by his previous tests. In closing his paper, he takes a very sane view of the possible uses and abuses of admixtures, which I will quote in closing:

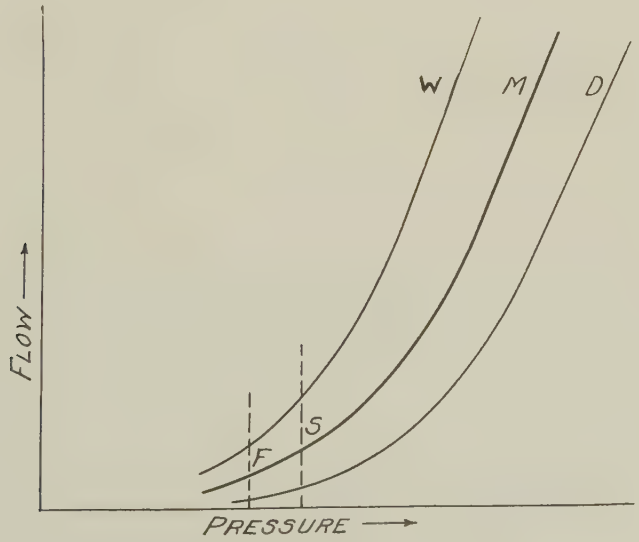
While admixtures are relatively more efficient than cement in obtaining a concrete of workability suited to any given condition of transportation and placement, the writer does not suggest that their use is always necessary or advisable. For concrete of any required cement content first attention should be directed to the most desirable sand-gravel ratio. Relative increase in sand content increases mortar volume which in turn permits the use of a less fluid mortar, thereby increasing workability and postponing likelihood of segregation. After adjusting the sand-gravel ratio and finding segregation under the conditions of use, or that the mix is near the segregation limit the use of an admixture will be advantageous. In work where a surface as true as the face of the mold is desired or in any case where the available fine aggregate is coarse and harsh, lacking in fine particles, the use of an admixture may be of value in obtaining satisfactory results.

The factors of strength and watertightness should not be forgotten. Generally these properties cannot be sacrificed to obtain workability. Tests which the writer has made quite definitely indicate that admixtures do not appreciably affect strength or permeability when used in the amounts or proportions specified by the manufacturer. In cases where excess quantities of an admixture are needed to produce satisfactory workability the possibility of reduction in strength and watertightness must receive consideration. On the basis of workability alone, the data in Table 1 would indicate the use of an admixture to be dependent mainly upon the relative cost of cements and admixtures. The use of admixtures 2 to 5 would not be economical unless their cost were less than twice, and No. 6 less than five or six times, the cost of portland cement. Consideration should also be given to the fact that cement not only increases workability as an admixture but at the same time it definitely increases strength and impermeability.

BY J. C. PEARSON

These valuable papers on slump and flow tests ought to be considered about the last word on the subject. They represent a very large amount of careful and painstaking work—how large can only be adequately realized by those who have studied the data closely. There are many interesting details worthy of attention, but this writer begs the privilege of departing from the usual custom, and of confining himself to a discussion of the present status of the workability problem and of the possibilities that are suggested by the data in the papers, and by certain experiments which have been carried out in the Research Laboratory of the Lehigh Portland Cement Co.

The outstanding feature of the papers by Smith-Benham and Lyse-Johnson is the demonstration that for concretes of different composition the ratio of slump to flow as measured on the flow-table is not constant, but increases with the richness of the mixtures. The significance of this important fact can be brought out on certain assumptions, if we consider briefly the characteristics of plastic materials.



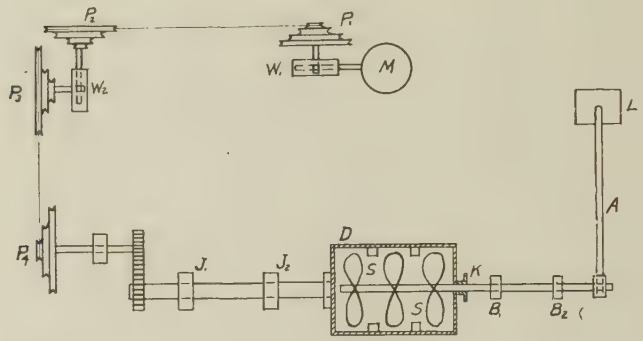


FIG. 1

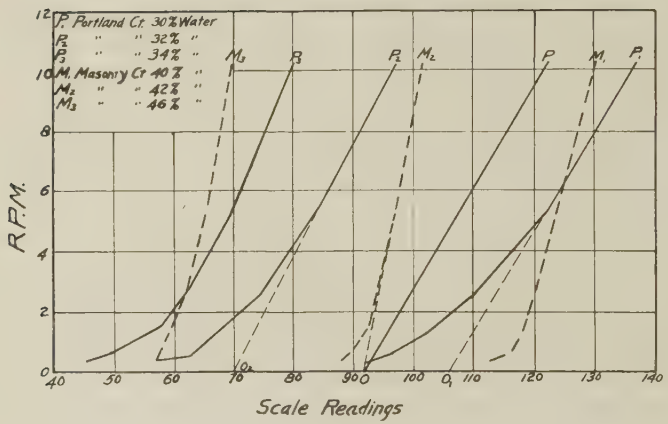

FIG. 2

If a mass of freshly mixed concrete could be forced out of a container through an orifice or a tube in such manner that the rate of shearing flow could be determined under different pressures we should expect to find the flow-pressure relations represented by a curve like one of those in Fig. 1. Confining ourselves for the moment to the heavy curve, M, we see that at first, for slight or moderate pressures, there would be no flow at all; at somewhat higher pressures the flow would be sluggish, but increasing with increase in pressure; and finally after the pressure had reached a certain value the relation of flow to pressure would become linear, or approximately so. I am not aware that an experiment of this

kind has ever been carried out successfully with concrete, but the relation is a typical one for plastic materials, and we have quite a lot of data substantiating the assumption that the relation holds for concrete.[1] The slope of the straight-line portion of the curve is commonly referred to as the "mobility," and we have found from a study of cement pastes that this factor of mobility is the one which seems most nearly allied to, and best adapted for, a comparative plasticity rating.

The upper portion of Fig. 2 illustrates a device used in our laboratory for studying the flow-force relations in cement pastes. A mixer drum, D, is mounted on the end of a stout shaft supported in the bearings J_1, J_2, and is driven by means of gears, belts, step pulleys, reducing units and a small constant speed motor, M. By simply changing the position of the belts the drum may be driven at 12 different speeds. Projecting into the drum through a low-friction packing gland, K, is another shaft supported in ball bearings, B_1, B_2, and blades or paddles, S, of different types, may be mounted on the shaft inside the drum. The outer end of this shaft carries a rigidly clamped arm, A, the far end of which rests on a platform balance, L. When the drum is filled with paste and put in rotation the blades, S, shear through the paste, and a certain resistance is set up by them which is indicated on the balance, L. Thus we have a system for measuring flow-force relations in which the speed of the drum is analagous to the rate of flow, and the reacting torque of the stator blades is the force.

Some typical results obtained with this device are shown in the lower portion of Fig. 2. The curves P_1, P_2, and P_3 were obtained from portland cement pastes containing different amounts of water; the curves M_1, M_2 and M_3 were obtained from masonry cement pastes containing different amounts of water. What I wish to call attention to particularly in this figure is the fact that change in the water content of the pastes shifts the curves to the right or left on the diagram with only a slight change in their slopes. This slight change in slope enables the interpolation of a curve with an intermediate slope, such as the line OP, which may be compared directly with the slope of the line OM_2, having the same intercept on the pressure axis. Now we believe that when

[1]Purrington & Loring obtained curves of this general type for concrete by measuring the power input and speed of a mixer. See A. S. T. M. Proceedings Vol. 30, Pt. II, p. 654-667, 1930.

two pastes are compared in this manner, the one which gives the greater slope, that is, the one which has the higher mobility, is the more plastic. The physical significance of this is that if one paste is more plastic than another, it shears more easily and flows more readily than the other when it is mixed in a pan or spread with a trowel. Furthermore, experience indicates that this property of the paste is carried over into mortars and concretes, and the degree of it that manifests itself depends upon the quantity of the paste in proportion to the aggregates, and also to a greater or less extent upon other factors, such as the grading of the aggregates, the presence of admixtures, etc.

This presentation is already familiar to some of you who are members of A. S. T. M. Committee C-9, but I have gone into the matter of these paste tests in some detail because of its direct bearing on the question under discussion. Returning now to Fig. 1, we may show why the flow and slump tests function as they do, under certain assumptions. The effective force that produces flow in a mass of concrete on a flow table is small, corresponding to a low pressure value on the diagram. The point F on the typical curve M may be taken to represent the region in which the flow table operates, corresponding to a relatively small deformation in the concrete. In the slump test the effective force tending to cause subsidence of the cone corresponds to a somewhat higher value on the diagram, represented, let us say, by the abscissa of the point S. Now in a given mixture, as shown above for pastes, moderate change in water content would be expected to shift the curve to the left (for wetter consistency), or to the right (for drier consistency), and the change in flow would be roughly proportional to the change in slump, as shown in Smith and Benham's Fig. 8, or in Lyse and Johnson's Figs. 5 to 8. That the change in slump should be more sensitive than the change in flow is also clearly indicated from the relative lengths of the ordinates through F and S and included between the curves W and D.

It has been shown in Fig. 2 that what we may call the intrinsic plasticity of a mixture (meaning that part contributed by or characteristic of the solids) is indicated by the steepness of the flow-pressure curve. Hence if we have different concretes

varying from lean to rich, or from harsh to plastic, and gage them to the same flow on the flow table, their flow-pressure curves will be somewhat as represented in Fig. 3. The point F represents the

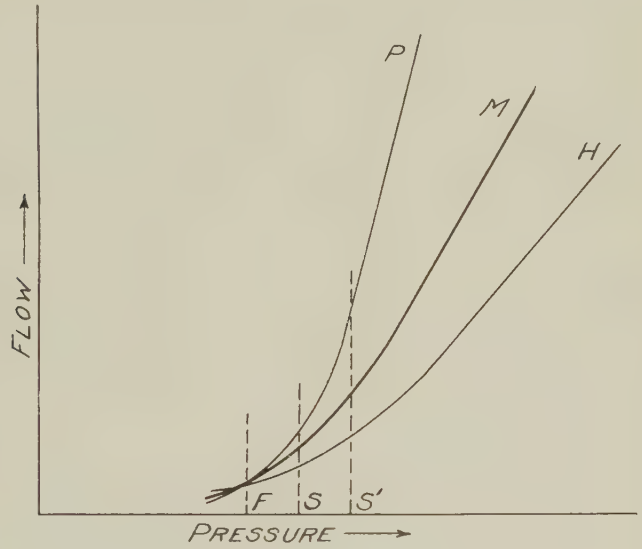

FIG. 3

force applied in the flow table test, at which point all have the same flow; the point S represents the force applied in the slump test, and it is evident at once that the plastic concretes should slump more than harsh concretes, just as the tests reported in these papers have shown.

The point of all this is that no single measure of "consistency" can possibly tell the whole story, as W. H. Herschel has so frequently insisted in his A. S. T. M. discussions[1] of papers on this general subject. If the slump test were not so crude and so lacking in dependable reproductibility, we could, as Lyse and Johnson have so ably pointed out, get some notion of relative plasticity by careful comparisons of flow-table and slump tests. But the slump test greatly needs improvement to bring about reasonable reproducibility. A complete mechanization of the

[1]See A. S. T. M. Proceedings, Vol. 25, Pt. II, p. 216, 1925; Vol. 28, Pt. II, p. 522, 1928; Vol. 29, Pt. II, p. 871, 1929.

test might help considerably, and we should be in a still better position if we could devise a more effective device, such for example as would yield the higher flows corresponding to the abscissa S′ in Fig. 3. Obviously the more points that can be obtained in these flow-pressure curves, the more certain we shall be of the characteristics of the mixtures studied.

This discussion is not intended to be discouraging to those who are interested in the practical problem of consistency control. A moderately improved slump test or a simplified flow test will serve this purpose very nicely. But for those who are interested in finding out how the workability of different mixtures can be compared and improved economically without sacrifice of other essential qualities, and what part admixtures and aggregate gradings and types contribute to this property, no single test will suffice. The ideal scheme would be to have some device that would furnish a number of well-defined points on these flow-pressure curves, but up-to-date we have found no satisfactory scheme of handling a batch of concrete in such way as to measure both force and rate of flow. Failing in this we have attempted to improve on the slump test, in the hope of using the improved test in connection with the flow-table, and thus getting two fairly definite points on the curves. But to date we have failed to overcome an undesirable lack of reproducibility, which is one of our main objections to the slump test.

The more we ponder upon this problem, the more likely it seems to us that some comparatively simple device will be developed, by means of which two or more definite applications of force can be applied to a mass of concrete, and the corresponding rates of flow measured, at least in relative terms. Perhaps we will make more progress if we deliberately turn our backs upon the present slump and flow tests and keep our thoughts focused on those fundamental relations that we want to bring out.

BY G. A. SMITH*

First I wish to consider the subject of workability of concrete in a general way. I do wish, however, to point out that, at the time our paper was presented, the sole purpose was to show that the slump test and the flow test, both used to measure the same

*Convention presentation by George A. Conahey.

property or condition of concrete, namely wetness, do not function to give comparable results. Since there was a lack of correlation in results as the mix was varied, there is conclusive evidence to the effect that other properties of the concrete were having some influence on the values obtained. I hope to take up this phase of the subject later in a separate discussion of the paper by Messrs. Lyse and Johnson.

Prof. Williams has brought out a very interesting point in the consideration of workability. Though I agree with him that segregation plays a large part when studying the property, workability, I believe that it is only one factor influencing the placeability of concrete.

First, what do we mean by workability? I am of the opinion that this involves much more than a simple consideration of the condition of the fresh concrete. In order that concrete may be of service it must be placed in the forms. For the service rendered to be of the highest quality, it is necessary that the ingredients of the concrete be uniformly distributed throughout the member. Were it possible to place concrete without effort so that a uniform and homogeneous member would result there would be no need to consider the question of workability or let us say placeability. The fact remains that concrete cannot be placed to give a satisfactory finished structure without the expenditure of effort. When I say satisfactory finished product I do not mean one which an unscrupulous artisan would pass, but one that comes as near being perfect as it is possible to make it. Uniform distribution of ingredients, complete filling of all intricate parts of the mold, and freedom from open porous structure, are conditions that must be fulfilled in the satisfactory product.

Since effort must be spent in placing concrete, be it supplied by man power, or otherwise, it is an item of cost and must be given its proportion of consideration. The amount of effort required is variable depending on the character of the concrete and the condition under which it is being placed. For example, rich mixes are recognized as being more workable than lean mixes. Concrete suitable for reinforced members is usually too wet for constructing roads, and 6-in. cobbles which are entirely satisfactory in massive structures would result in anything but a workable concrete where intricate steel fabrication and relatively

small members are concerned. Suitability for the purpose intended makes the question of workability a relative one, as Prof. Williams points out but there is ever present the fact that under all conditions work must be done to effect satisfactory placement.

Abstractly any mass of material may be workable but one may be more workable than another depending upon the amount of effort or work necessary to accomplish a definite end. In the case of concrete any mass of concrete can be worked or placed but the amount of work necessary to effect a given condition in the final product differentiates between two mixes as to their relative workability. The mass that can be placed with the least effort will be the most workable.

When placing concrete it is necessary to move small parts of the mass to remove entrained air and effect a satisfactory placement. This presupposes a non-segregating mix. In the case of a segregating mix though the concrete may fill the form fairly readily and without material effort there enters the question of distribution of the materials. If segregation has occurred, it means that a large amount of effort must be expended to bring about a redistribution of the ingredients if the satisfactory structure is to result. The remixing in the forms may be so arduous a task that it is not accomplished and the result is an inferior product. The additional work required in the case of a segregating mix may be much more than that in a mix apparently less easily worked but relatively non-segregating.

To my mind the term workability involves the question of the amount of work necessary in placing the concrete to accomplish a satisfactory finished product. On this basis segregation destroys the homogeneity of the mix and necessarily contributes to a non-workable condition requiring more work to bring about the condition we desire. The workability of a concrete, therefore, is the resultant of two factors: (1) The ease with which the aggregate particles and small parts of the concrete mass may be moved relative to each other, and (2) Cohesion within the mass or lack of segregation.

The ease, under a given condition of placement, with which movements within the mass are accomplished is dependent on the size, shape and surface characteristics of the aggregate particles and the quantity, quality and characteristics of the medium in

which they are distributed. Cohesion or lack of segregation is dependent on the same factors as those influencing the ease of movement but they do not always function in the same direction to affect the amount of work necessary to place the concrete. For example, increasing the quantity of cement, consistency and other conditions remaining constant, increases both the ease of movement and cohesion within the mass. On the other hand increasing the quantity of mixing water increases the ease of movement under a condition of uniform distribution but decreases the cohesion.

There is no need to enumerate the various items incident to the manufacture of concrete that influence workability. Each and every condition has its effect. Most of these have been discussed before this Institute and any further discussion would be superfluous. The question of admixtures and their functioning, appears to be a major consideration for this discussion. This phase I wish to discuss briefly, not with the view of comparing various admixtures but to point out what an admixture may do to improve conditions.

In any design certain conditions are laid down and under these it is expected that the requirements for the job will be met. Any addition of material to the designed mix which will influence the placeability or workability in a beneficial way may be deemed an admixture. This may be additional cement, increased quantity of mixing water, a combination of the two or some other material of merit. Should any change be made by such additions there are two conditions that must be met: (1) the quality of the resulting concrete must be unimpaired. (2) The workability of the concrete should be so improved that the placing may be expedited and result in a superior finished product.

It is generally conceded that added cement has a beneficial effect on the workability and we, not infrequently hear of an additional sack of cement being used because of its effect. The answer to this is not difficult. Since cement in reasonable amounts is necessary for a moderate degree of workability, increasing the cement paste in quantity and quality, consistency or wetness remaining constant, the ease of displacement and the cohesion in the mass are increased.

Water used to increase workability is a most unreliable admixture. Though a certain amount is necessary, depending on the job conditions, any quantity in excess of this amount is injurious to the finished product and may go so far as to cause a negative result so far as workability is concerned. Displacement in a plastic mix may be more difficult than in a wet mix but lack of cohesion in the wet mix results in segregation and additional work to effect satisfactory placement.

Other materials to be added to a mix, normally thought of as admixtures, should function to increase the ease of placement and to improve the condition of the finished product. Some materials are more effective to this end than are others just as one cement may result in a more workable concrete than another. It was pointed out that both ease of movement within the mass and segregation were dependent on the quantity, quality and characteristics of the cement paste and characteristics of the aggregates. Since the aggregates are inert, admixtures would not have any effect on them as such. The only phase they can influence is that of the cement paste.

The addition of any finely divided material and the addition of the necessary water to maintain a constant consistency tend to increase the volume of the paste. This increase in the volume of paste permits a wider separation of the aggregate particles and a consequent reduction in the resistance to internal movement. Plastic properties of the paste and concrete mass as a whole may be improved depending on the characteristics of the admixture used. Reference has been made to the fat, smooth condition noticed in concrete containing some admixtures. This condition, since it parallels that observed when the richness of a mix is increased, not only increases the ease of internal movement but also decreases segregation by increasing the cohesion within the mass.

The advantages to be derived from improving workability though not always tangible are nevertheless real. Expediting the placement and overcoming unsightly honey combing which requires patching are tangible enough in themselves but the effect of non-uniform distribution of materials which affects the durability and stability of a structure are not always apparent until it is too late to remedy matters.

It is hoped that this discussion may be helpful in bringing about a unification of ideas relative to the property, workability, so that before long when the term is used we may each have a more clear cut idea of what is meant.

The fact that the value of workability is appreciated leads me to the belief that, eventually, it will be analyzed and that a full and complete understanding will be reached.

Someone may ask the question; How is the property to be evaluated? To evaluate the property and put it on a mathematical basis would require some means for measuring the work necessary to effect satisfactory placement. Numerous attempts have been made toward this end and, if they have shown nothing more, they indicate that under comparable conditions concretes of different compositions have different properties so far as the placeability is concerned. This is an every day observation in the laboratory. When casting specimens it is observed that more effort is required to rod one concrete than is required for another. This is brought about by variation in the distribution and the resistance of the mass to the penetration of the rod. Though differentiation between mixes when rodding is at times an easy matter, it is only a relative condition that is noted and the measurement is purely qualitative. I believe that an evaluation of the rodding effort would come as near being a measure of the property as anything that could be devised. In fact this is the basic idea back of the penetration apparatus. I have used this apparatus in studying the effects of numerous admixtures and the effects of varying the proportions, grading, consistency, etc., and have obtained indices for the workability which appear to parallel interpretation as to the relative workability of the concretes considered.

In conclusion I wish to say that, with the extensive thought and consideration now being given to this phase of concrete it is my firm conviction we will not have to wait long for an answer to some of our problems. We will have in the near future a definite correlation of ideas on the subject and an accepted method of evaluating separately, if not collectively, the two factors governing workability namely, ease of movement in the mass and segregation.

DISCUSSION OF LYSE AND JOHNSON PAPER BY G. A. SMITH

The editorial comment introducing the two papers, one by Messrs. Lyse and Johnson on the subject of the consistency of concrete and the other by Mr. Benham and the writer, creates an erroneous impression relative to the attitude of the several authors. The comment indicates that the writer favors the flow-table as a yardstick for measuring workability whereas Messrs. Lyse and Johnson favor the slump test. I wish to point out that in no instance in the paper "A Study of the Flow-Table and the Slump Test" was the flow-table indicated as a measure of workability. The authors certainly did not at any time have in mind indicating that either test is a measure of workability when concretes of different compositions are considered. When referring to the property or condition that was being measured the terms consistency and wetness were used.

Though the workability of *a given mix* will vary, within limits, with the quantity of water used or with the wetness as indicated by either the slump or the flow, the workabilities of two different mixes gaged to either the same slump or to the same flow may be entirely different. The point is, that workability and wetness (consistency) are not synonymous under all conditions. In this case the use of the two conditions or properties interchangeably leads to a misunderstanding and a misrepresentation of the authors' conclusions. I quote from the last paragraph of the conclusions: "The data on the whole indicate that, where a consistent indication of the consistency or wetness of concrete is desired, the flow test is preferable to the slump test because of its more nearly uniform functioning." The only condition indicated is *consistency* or wetness.

The Editor in introducing the two papers asks, who can discover a common ground. It appears to me that both papers have very much in common and when properly interpreted will indicate the same conditions and that the same conclusions may be reached from either paper.

It was with a great deal of pleasure and interest that I reviewed the paper "A Study of the Slump and Flow of Concrete." Particularly because Messrs. Lyse and Johnson showed tendencies of results where conditions were comparable that paralleled those

observed from our tests. No comment is necessary in these instances. On the other hand there are one or two conditions on which I wish to comment.

The authors indicate that the use of the slump specimen in determining the flow results in larger flows and consequently is a more sensitive measure than is the flow obtained with the usual flow mold. This is quite obvious but it has little to do with the apparatus or the condition of the concrete. It is largely a question of mathematics. Consider the conditions existing in the test. The volume of concrete in the flow specimen is about 0.16 cu. ft. and the basic diameter is ten inches. In the slump specimen there is approximately 0.20 cu. ft. of concrete and the basic diameter is eight inches. Other conditions being equal it is seen that the flow increase in diameter with the slump specimen should be about 1.6 times as great as that using the flow specimen. There is, however, the effect of the additional head and that of the erratic functioning of the slump test which tends to give a greater spread. The increased head due to the height of the slump specimen does not appear to have a large effect since the ratio of the increase in flow for the slump specimen to that for the flow specimen between the zero and the five drops (Figs. 1, 2 and 3) varies from less than 1.0 to 1.7 averaging less than 1.3. Were the functioning consistent the increase in flow would be about 1.6. The functioning of the slump test has been discussed in the paper by Mr. Benham and the writer. It was pointed out that in the wetter mixes the concrete flowed down and out and the test was not a true slump. In the tests by Lyse and Johnson this same condition undoubtedly existed as is evidenced by the high flows at zero drops and was unquestionably responsible for at least a part of the increased flow observed. Personally, the writer is inclined to favor flows of lower magnitude because of the more nearly rectilinear relation that exists between flow and the quantity of water used. After the mass of concrete has spread a certain amount this relation no longer exists but becomes a curvilinear relation since the area covered by the sample varies as the square of the diameter. No specific example can be cited but it is readily seen that during the early flow there is a reserve supply of sample which is apparently used up in compensating

for the increased area. After this reserve has been used and the concrete has spread to nearly uniform thickness proportionate changes in diameter become less for increased manipulation and for additional quantity of mixing water. This is evidenced by the diminished rate of flow with increased number of drops for the wetter consistencies, (See Figs. 1, 2 and 3 of Lyse and Johnson paper) as well as lowered increased in flow for a given increase in water.

Lyse and Johnson make numerous references throughout the discussion and in their conclusions to the effect that the slump test is superior to the flow test for measuring workability. This is based on the observation that for a given flow the slump for the richer and more workable mixes was greater than that for the less workable mixes. The variation in slump with observed improvement in workability, the flow being constant, was observed and pointed out by the writer.

It is believed that the difference in slump, flow or consistency or wetness being constant does parallel improvement in workability. However, to say that, because of this, the slump is superior to the flow as a measure of workability is far from being logical. Let us consider the converse of this condition of equal flows and variable slumps. For equal slumps and flow would be less for the more workable mixes. It would be, then, just as logical to say that the flow was a more sensitive measure of workability, the workability varying inversely as the difference in flow.

Neither test in itself can be used as a criterion. Supposing that either the slumps or the flows were constant for two mixes, one lean and the other rich. The fact that the slumps were constant according to the authors would indicate that one was equally as workable as the other. This we know is not the case. Each of the methods is a measure of the wetness or consistency of the concrete and individually for a given mix is a measure of the relative fluidity of the mix. The only correlation between slump or flow and workability is in the case of a given mix. With a variation in quantity of water both the slump and the flow vary and so does the workability within limits. Mixes varying in proportions with variable materials cannot be correlated as to

relative workability by either of the test methods used independently.

In conclusion I believe that the Editor's question has been answered and that we find far more in common in the two papers than there is in disagreement. There is one differentiation that must be made relative to two properties of concrete. Under different conditions of composition and under variable conditions as relate to the properties of the separate ingredients of concrete, it is absolutely necessary to distinguish between fluidity, wetness, consistency or whatever we choose to call it and the workability. Once this is done we will be in a position to study the effects various materials and variations in materials have on the workability or the placeability of concrete.

BY DONALD M. BURMISTER*

These two papers are valuable contributions to the study of concrete mixtures and contain very complete data showing the variation of slump and flow resulting from changes in cement and water content in various concrete mixes. The interpretation of the data by the writer leads to the conclusion that these tests measure different properties of the concrete mixtures, both of which, however, must be included in any criteria for workability. In the following discussion the writer presents a study of these data and suggests a means of combining the test results in order to arrive at a measure involving both properties of concrete.

The handling and placing properties of concrete may be expressed in two ways, first on the basis of the effort and time to produce the finished product, and second on the basis of observed effects of certain characteristics by which workability may be judged. The properties of concrete are reflected in varying degrees in its behavior in every test made upon it as well as upon the job. Its more or less fluid nature imparts flow characteristics. Its semi-plastic nature imparts smoothness and mobility. These two qualities together determine to a large extent the workability of concrete. These qualities as criteria of workability in concrete may be used as bases of design of concrete mixtures or of the comparison of concretes.

In order to evaluate the slump and flow tests, it is necessary to determine how these two tests function and which qualities of

*Instructor in Civil Engineering, Columbia University. His discussion was presented at the Convention by title only.

a concrete mix have the greater relative effect, for which that test then may be taken as a relative measure.

The flow table—Primarily the flow table brings out the fluidity of the concrete due to wetness. Flow is a property of a fluid condition. A more or less true flow is produced by the work performed upon the concrete when the mass has been broken down or has slumped down, so that a quite uniform slope exists radially outward from the center.

This is indicated in Fig. 1, 2, and 3, by Messrs. Lyse and Johnson, who have plotted in the lower right hand quarter of each figure the effect of the number of ½-in. drops of the flow table upon the flow, using the flow cone. The effect of some slumping action in increasing the flow from zero to five drops is shown in nearly every case by the greater steepness of the curves in this range. Thereafter the curves assume an almost uniform slope, showing that the flows for successive drops were very nearly equal, and were proportional to the work performed upon the concrete. Therefore a better measure of wetness is obtained by the larger number of drops, for instance ten or fifteen.

It seems to the writer that a better and more sensitive measure of wetness is obtained by using that half of the circumference of the concrete mass, on which the greatest flow occurs as the average figure. The lopsided flow, if the flow cone has been properly centered, is an exaggerated condition, due mainly to non-uniformity of depositing the concrete. But this condition may reflect a harshness and a tendency toward segregation in the concrete. The uniform slope of the curve mentioned above and the almost regular increase in flow with increase in wetness shows that the flow table measures the wetness of concrete.

The slump cone—The slump cone measures primarily the plasticity of a concrete, which is imparted to the mass by the fine material in the mortar, whether it be cement, silt and clay, or other admixtures. The differences in the properties and the behavior of workable concretes and those classified as non-workable are largely due to this fine material, which acts as a lubricant and more important still tends to retain all of the mixing water within the mass. Consequently smoothness and mobility are imparted to the concrete, which varies with the amount and the kind of this fine material and also with the amount of mixing water.

In plastic concrete the particles of coarse aggregate, when separated by sufficient plastic mortar, flow more smoothly over one another than in a non-plastic harsh one, because of the low shearing resistance. Consequently the mass as a whole deforms more readily. Therefore under the action of gravity the plastic concrete will slump more for the same degree of wetness.

The slump cone gives a real measure of this quality plasticity only when a true slump is obtained as indicated in types 1 and 2 by Messrs. Smith and Benham. If type 4, in which the concrete slushes down leaving a compacted core, indicates anything, it shows that there has been a breakdown in the binding properties of the mortar, due to an excess of mixing water in relation to the given mix. There will therefore be a greater tendency for segregation and for the leaking of the liquid from the concrete.

In these two tests two qualities have been relatively measured, or rather the effects of these two qualities:

1. The flow table reflects the wetness of the concrete.

2. The slump test reflects the plasticity of the concrete. Of course in both tests both qualities have some effect, but the nature of the tests are such as to bring out the particular quality more effectually.

A method of relatively evaluating the effects of these characteristics of concrete is outlined, resulting in the plasticity coefficient, which is suggested by the writer as an index or yardstick of relative workability. For any given concrete the plasticity coefficient is the ratio of the slump in inches to the inches of radial flow on the flow table.

The Plasticity Coefficient equals $\frac{\text{Slump in inches}}{\text{Radial flow in inches}}$. It reflects the relative plasticity and wetness of the concrete and is indicative of the behavior of concrete during handling and placing. The purpose of such an index is to provide a figure which will be indicative of the characteristics, and one which may be used as a basis of comparison and design of concretes, which the slump or flow alone have not effectually done. The properties and behavior of any concrete are made more tangible and the concrete is more completely defined by:

1. The plasticity coefficient and the flow. or

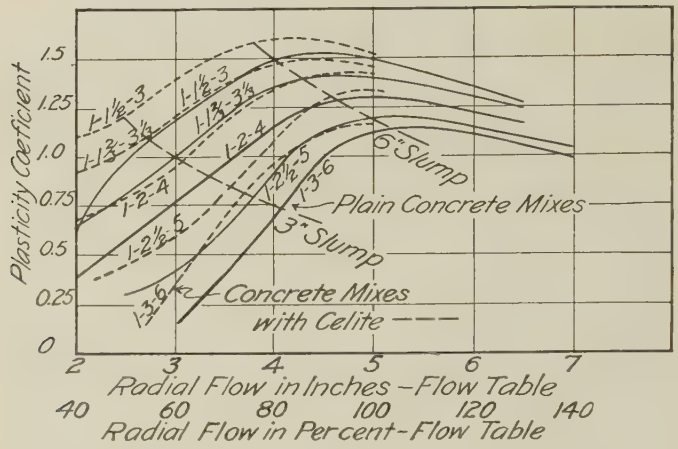

FIG. 1—RELATIONS OF PLASTICITY COEFFICIENT, FLOW AND MIX

2. The plasticity coefficient and the slump.

When the curves in Fig. 8, "Relation between Flow and Slump" by Messrs. Smith and Benham are replotted with the plasticity coefficient as ordinates and the corresponding flows for the different mixes as abscissas, a most interesting set of curves results. The flow is chosen rather than the slump because the

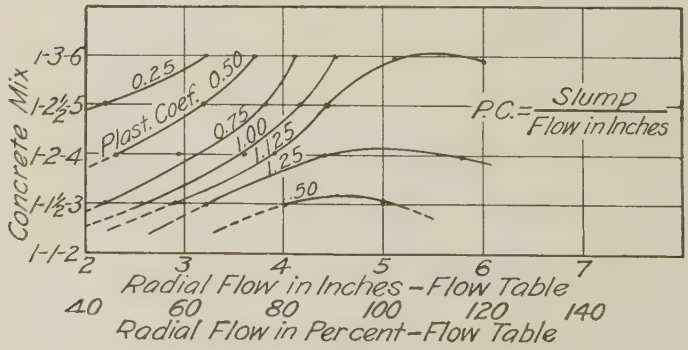

FIG. 2—THE VARIATION OF THE PLASTICITY COEFFICIENT WITH FLOW FOR PLAIN CONCRETE

range is greater and the curves bring out certain facts better. A flow of 100 per cent on the flow cone of ten inches in diameter, for instance, corresponds to a radial outward flow of five inches, and others in proportion. The data taken from these curves is tabulated in Tables 1 and 2.

These results have been plotted in Fig. 1, showing the relation of the plasticity coefficient, flow and mix. They have been replotted from the curves of Fig. 1 in a different form in Fig. 2, which brings out better the relations existing between these factors.

The following conclusions are obtained from these curves.

1. The plasticity coefficient increases with the richness of the concrete. A high plasticity coefficient, as a criterion of the desirable qualities of concrete, is indicative of a uniform and homogeneous product with little tendency to segregate.

2. The plasticity coefficient also increases with the addition of water up to some maximum point, which is the limit of workability for that concrete. However, this maximum point probably results from the fact that the slump test ceases to function as such for slumps greater than seven inches.

3. The addition of Celite as an admixture increases the plasticity coefficient, and that for a given flow concrete with Celite admixture has the equivalent plasticity coefficient of a much richer mix, as indicated by the relative positions of the curves, thus indicating an increase of workability.

4. The two figures plasticity coefficient and flow or slump are quite definitely indicative of the relative ease with which a concrete may be handled and placed, and are therefore bases for the comparison of concretes, as to their handling and placing properties.

5. A low plasticity coefficient either indicates lean watery concrete which is harsh and will tend to segregate badly, or it indicates a very dry harsh mix which is difficult to place. Any considerable working to make such concretes flow into form work will only aggravate its undesirable tendencies.

6. In Fig. 1 two lines have been plotted showing the relation of slumps of 3 and 6 in. to both the plasticity coefficient and flow. These show that for equal slumps the leaner mixes are much wetter and more fluid than the richer mixes as indicated by their

respective flows, and also the plasticity coefficients are lower for the leaner mixes. Considering equal flows, the richer mixes have greater slumps and the greater plasticity coefficients, and there-

Note—Pl. C. is the Plasticity Coefficient

fore possess more of the desirable qualities by which workability is judged.

7. Similar curves for other materials will reflect the effect of grading and proportions upon the workability of the concrete made from them.

Basis of comparison—In classifying a concrete it may be more plastic and less wet or it may be wetter and less plastic. Any real basis of comparison must rest upon measures of both of these characteristics in concrete. The two concretes are quite different in their properties and behavior and are judged accordingly as to their relative workabilities. From the foregoing discussion it is seen that there are two bases of comparison of concretes, that are quite definite and simple of application.

1. The comparison of plasticity coefficients for equal flows.

2. The comparison of plasticity coefficients for equal slumps. The ones with the greater plasticity coefficients have more of the desirable qualities by which workability in concrete is judged.

Basis of design—From the design standpoint there are two simple requirements which can be specified in addition to the water-cement ratio governing strength.

1. A minimum value for the plasticity coefficient consistent with the class of concrete and the field conditions.

2. A maximum flow or slump suitable for the given field conditions.

In meeting these requirements a concrete of pretty definite characteristics and uniformity is obtained. In this connection the curves in Fig. 2 are very useful, or similar ones. For example, if a flow of 70 per cent or 3½ inches on the flow table was desirable and suitable for the given field conditions and further if a plasticity coefficient of at least 1.00 was specified, the leanest mix that could be used for the given materials and proportions of aggregates would be a 1:2:4 plain concrete. The necessary slump that must be obtained is readily found from the relation—
Slump equals Pl. C x Flow in inches.

This simply means that the concrete has the desired properties and workability for the given job, when the flow is 3½ in. and when the slump is also 3½ in. at the same time. To meet both criteria at the same time in a concrete mix is to ensure the quality specified, whether obtained by the use of more cement,

admixtures, or better by such gradings and proportions of the aggregates as are necessary. This may be accomplished by trial methods, starting with a cement paste of given water-cement ratio, as specified for strength. When the mix has been properly designed, using both tests to fix its characteristics, then the proper field control may be maintained by means of the slump test alone, as an indication of the uniformity of the output.

Thus by combining the results of the flow table and the slump tests, the properties and behavior of any concrete are made more tangible and the criteria of plasticity coefficient and flow or slump serves as a more definite basis for designing concrete mixtures and for the comparison of different concretes.

BY F. O. ANDEREGG

The method of attack on the workability problem proposed by Mr. Pearson of using the pressure-flow rate curve is, I believe, the best that has so far been suggested. After seeing these curves it is obvious why the slump result may not be consistent with the flow table finding. It should be pointed out, however, that the flow rate is usually linear while both slump and flow table measure flow in two dimensions.

The best definition of workability involves both ease of working the concrete into place and freedom from segregation. The latter is a result of improper grading somewhere in the system: The water may flow from the cement if the latter is not properly ground; the cement paste may have a tendency toward oozing out of the sand if the latter is improperly graded; and finally, the mortar and coarse aggregate may separate from each other.

By building up a system with a proper gradation of sizes we have in the first place a sort of filter which prevents segregation. It is a little like a sand filter except that here we want a system where large particles serve as a sort of anchor or key holding back the next smaller size and so on down to the finest cement particles. In turn all the smaller sizes act as ball bearings permitting the ready rolling of the next larger into place.

The result is a maximum of ease of placing, a minimum of segregation, together with a maximum of packing and very good workability is secured with a minimum of lubricating water.

To secure this ideal grading use a set of Tyler standard screens differing in opening dimension by the factors and the ratio of fractions on the separate sieves is constant at about 1.2, the increase in weight (or absolute volume) being greater as the sizes increase. This ratio is affected slightly by the shape of the particles.

On a basis of the ideal grading we can go ahead logically with the analysis of the workability of commercial concretes. The latter differ from the ideal by gaps in the grading curve, or humps where too great a preponderance of one size occurs, or in combinations of the two. The procedure would then be to determine complete pressure-flow rate curves at several degrees of wetness for ideally graded materials and then introduce systematically humps and gaps into the curve, and determine the effect. When sufficient experience has been accumulated, one should be able to predict accurately what any given commercial grading will do and give it a grade, say 50 per cent or 70 per cent of the ideal.

On a basis of an ideal grading it is not difficult to secure an understanding of the role of *admixtures,* other than specific waterproofing materials or hardeners. If the cement is not ground to approximate the ideal (and few cements are in the very fine region) a finely ground, well-graded admixture may aid in filling voids and serving as ball-bearings. In this way a real improvement may be made.

Again, if the aggregates are quite harsh it is necessary to provide a greater bulk of paste to prevent segregation and containing more lubricating water. With bentonite clays and diatomaceous earths we can get more lubricating water into the system. At the same time the water-cement ratio is increased and whether the addition effects an all-around improvement depends upon the grading curve for the whole system, cement-sand-coarse aggregate. With properly ground cement and properly graded aggregate an admixture would be not only superfluous, but actually harmful.

FURTHER DATA WITH DISCUSSION FROM G. M. WILLIAMS

The writer has not at this writing seen the discussion relating to his paper "Admixtures and Workability of Concrete" but some of the criticisms and questions may be partially answered

by the following data obtained in tests with a type of admixture which was not represented in the original tests.

The writer's definition of workability and the effect of admixtures is summarized as: By workability is meant the ability of a concrete mixture to remain homogeneous and free from segregation during the process of transportation and placement. A non-segregating mix, having necessary flowability, is a workable mix. Segregation is influenced by quality and quantity of mortar in the mix and occurs when mortar is so fluid that it cannot adhere to the large aggregate particles and hold them in suspension, or when the relative mortar content is too small. Workability increases and segregation decreases as volume of mortar increases which results in a heavier, stickier, better adhering mortar without loss of necessary flowability. Various powdered admixtures including portland cement, were found effective in increasing relative mortar volume but their efficiencies varied greatly. The efficiencies were approximately proportional to the volumes of pastes formed when equal weights of admixtures were brought to the same flowabilities. Identical concretes containing equal volumes of admixture pastes were found to result in practically the same segregations as measured by spread of aggregate beyond the mortar line in the flow table.

While one admixture used in the original tests contained a percentage of bentonite or colloidal clay its behaviour was not the same as has been found for Colloy and Aquagel, two colloidal clays which are representative of this type. While some work has been done with both of these materials the data following relates mainly to the use of Colloy as an admixture to increase workability.

Colloidal clays or bentonite have the property of absorbing many times their weight of water, resulting in the formation of a very large paste volume. When used as an admixture in concrete a large increase in mortar volume should be expected, due to the addition of a relatively small weight of the material in powder form. Volumes of pastes formed by the addition of water up to 300 per cent by weight are shown for Colloy, Aquagel and Celite in Fig. 1. This water quantity is just beyond the saturation limit for Celite. It will be noted that the volumes are practically the same and proportional to water content up to this limit.

Comparing Celite and Colloy identical concretes were prepared to which were added equal weights of admixtures. Flowabilities were made equal, amount of segregation noted, and mortar volumes computed as listed in Table 1.

TABLE 1—AVERAGE MORTAR VOLUMES AND AMOUNTS OF SEGREGATION FOR EQUAL WEIGHTS OF ADMIXTURES

Weight of Admixture grams	Volume Mortar c. c.	Increase in Mortar Volume due to Admixture c. c.	Added Mixing Water Required by Admixture grams	Segregation of Coarse Aggregate grams	Flowability
0	763	...	...	197	177
48 Colloy	821	58	38	148	174
48 Celite	883	120	100	41	175

As indicated in Table 1 the large volume increase in mortar content which would be expected for Colloy did not result. The foregoing figures indicate that approximately 100 grams of Colloy would be needed under these conditions of test to furnish a mortar volume resulting from the use of 48 grams of Celite.

In Table 2 are shown the results when the Colloy content was adjusted to furnish the same mortar volume.

TABLE 2—AVERAGE MORTAR VOLUMES AND AMOUNTS OF SEGREGATION ADMIXTURES PROPORTIONED FOR EQUAL MORTAR VOLUMES

Weight of Admixture grams	Mortar Volume c. c.	Segregation of Coarse Aggregate grams	Mixing Water c. c.	Flowability
100 Colloy	886	36	390	172
48 Celite	885	22	400	180

In the foregoing experiments the Colloy was added in dry powder form with the other constituents, as is the usual practice and as is recommended by the producer of this admixture. In no case, when this procedure was followed, was it possible to obtain the bulking effect for Colloy which would be expected from a study of Fig. 1. Similar results were also found for Aquagel.

However, when the admixture was pre-hydrated, by the formation of a paste prior to its addition to the volume of concrete, mortar volumes were increased in a manner which were considerably greater than could be predicted from Fig. 1. Results obtained by the two methods of adding the admixture are given in Table 3.

TABLE 3—COMPARISON OF MORTAR VOLUMES AND SEGREGATIONS OBTAINED WHEN COLLOY WAS ADDED AS (1) POWDER AND (2) A PASTE

Admixture	Total Mixing Water c. c.	Flow-ability	Volume Mortar c. c.	Segre-gation grams
48 Colloy (Powder)	365	192	840	100
48 Colloy (Paste)	565	187	1000	15

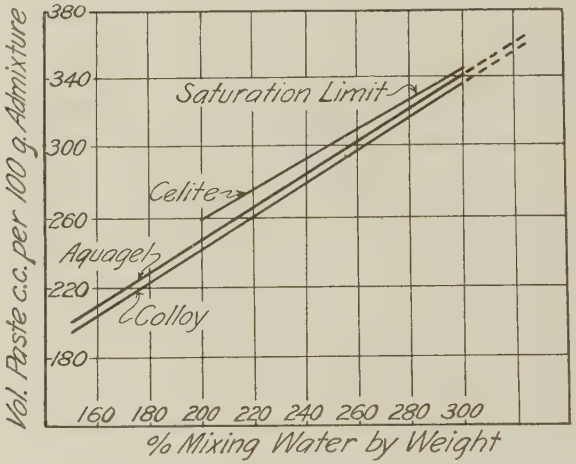

FIG. 1

The use of prehydrated Colloy resulted in the use of a greater total quantity of mixing water than was needed when the dry powder was added and in turn the mortar volume was greatly increased. The fact that some segregation occurred in spite of the large mortar volume in the batch, indicates this mortar to have lost some of its adhesiveness and power to hold the aggregate particles in suspension. The density or specific weight of this mortar must be less since water furnishes increase in volume, the solid content being the same.

The foregoing test results indicate that conclusion No. 2 of the original paper cannot be readily applied to admixtures of the bentonite type. Increase in volume with increase in water content in paste form is not a criterion of volume increase when the admixture is added to the concrete batch in the usual manner. If an admixture of the bentonite type is prehydrated before

addition to the mix its effect on mortar volume can be predicted from the volume of paste formed but this paste, due to its high water content, cannot be as efficient as one formed by the other types of admixtures, when compared volume for volume. The neat paste test will also fail in application to admixtures of the oil or tar type. Therefore it seems best to make use of the flow table segregation test directly in rating admixtures. Volume of paste formed is a matter of computation, and efficiency of the mortar in retaining and holding aggregate particles can be measured quantitatively by noting segregation. If mortars are dissimilar as may be the case in comparing a bentonite mortar with a Celite mortar, admixture quantities can be adjusted until the segregation is the same before decision as to relative efficiencies is made. In this manner the flow table segregation test can be employed to determine the efficiency of any admixture, whatever its type, and the procedure outlined above and in the original paper may be summarized as follows:

Step No. 1—Prepare a basic mixture of cement, graded sand and ¾-in. to ⅜-in. aggregate with the latter in excess so that when sufficient water is added to result in a non-fluid or segregating mortar (a plastic, adhesive mortar) there will be considerable segregation of coarse aggregate beyond the mortar line of the flow table.

Step No. 2—In addition to a basic mix plain concrete, prepare an additional batch for each admixture to be tested. Use specified quantities of admixtures and sufficient mixing water to result in the same flowability for all. Compute mortar volume of each batch and note the amount of segregation. Values obtained should be an average of at least three trials in which concordant results are obtained.

Step No. 3—Adjust admixture contents so as to furnish equal mortar volumes for each. Make flowabilities equal, compute mortar volumes and note segregations. After three concordant trials, if segregations are not approximately equal, further adjust admixture contents until equal segregations are obtained. Mortars lacking in density and adhesiveness to hold aggregate particles in the mass can be improved by the addition of more admixture in the case of powdered materials, which in turn tends to furnish a less fluid mortar of still greater volume without loss

of necessary flowability. Some adjustment of water content must be made with any change in admixture content when using materials of the powder type. In making the flow and segregation test particular care should be employed to insure uniformity in placement of concrete in the mold since those aggregate particles in the outer portion of the mass appear as segregated particles. Pockets of excess coarse material placed in the center of the mass will furnish too small segregation volumes and lead to improper conclusions.

Readers are referred to the JOURNAL *for Nov. 1931 (Vol. 28) for further discussion. All additional discussion should reach the Secretary by Oct. 1, 1931.*

Discussion of Report of Committee 108

"Properties of Mass Concrete"*

BY RAYMOND E. DAVIS†

The published report in the January Journal, is preliminary. I should like here to emphasize some of the things touched upon in the report and perhaps bring to your attention informally, certain other considerations, not previously presented. What I have to say will be more concerning what we do not know about mass concrete than what we do know. As a matter of fact, we know very little. Committee 108 was organized last spring because some of us felt the time had come to find out what is actually going on inside of concrete in large masses. The committee has done very little except to survey the field. The report presents a digest of material which has been gotten together by the committee giving available information which has been collected on various projects, principally in the field. The data have to do principally with dams—to some extent with other structures such as bridges and massive foundations. In examining the material, you will find that practically all of it has to do with the temperatures that have been observed to occur inside of these structures. We all know that cement and water, when mixed with aggregates to form concrete, evolve heat during the hardening process. In our small structures of thin sections, we do not notice that heat; but in the more massive structures, it becomes an important factor. We know something of the properties of concrete when cured at normal temperatures in small masses; but we do not know very much about the properties of concrete when cured at higher temperatures in large masses. Observations

*A. C. I. Journal, January 1931; *Proceedings*, Vol. 27, p. 385.

†Remarks by Professor Davis in formal presentation of his previously published Committee report to the 27th Annual Convention, Milwaukee, February 24-26, 1931. Following the Committee Chairman's introduction is the discussion, which will be continued in the Journal for November, 1931, V. 28.—Editor

made on various structures, even of the leaner concrete, show increases of temperature to 40 and 50 deg. above normal, or above the initial temperature of the concrete at the time of placing. With richer concrete we sometimes get increases of more than 100 deg.—in fact, in some cases, the cement paste boils. We have been taking it for granted that properties observed in concrete in small masses—properties of strength, elasticity, plasticity, durability, permeability—are to be found also in concrete of large masses, when, in point of fact, we do not know. To learn what we do not know in this regard is the job that faces our committee.

In the few tests made here and there in laboratories, notably some of the tests we have been making during the last couple of years, at the University of California, where we have specimen sizes up to one cubic yard, we have learned something of what happens to the strength under the temperature conditions that obtain inside the larger masses. We know that heat hastens the chemical process of hardening, and that at the early ages we get very much greater strength than at the normal standard temperature of 70 deg. But we know that concrete cured at the lower temperature gradually increases in strength until it passes that obtained with the higher temperatures that obtain inside the mass. In some cases there is a slight indication that there is a retrogression of strength when cured at the very high temperature. This Committee hopes to determine, both by laboratory tests and by field investigation, what is happening in our concrete structures and what are the properties of concrete cured in masses or under conditions simulating mass concrete. After concrete is placed, in a dam, for example, there is evolution of heat and the temperature rises. It continues to rise until the rate of heat evolution equals the rate of dissipation of heat, when the temperature curve, if you please, flattens out, becomes horizontal, and thereafter there is a gradual decline. In some of these structures the concrete does not come back to normal temperature until several years after placement. What are the stress conditions inside the structure? Certainly during the evolution of heat and increase in temperature there has been a tendency to expansion along the axis of the dam and then there is a compression, the concrete is then more or less in a plastic

state. It flows, if you please. When finally the peak has been reached, it is perhaps in a maximum state of compression, but thereafter, with the decline in temperature, there, a tension takes place before it gets back to normal temperature, and that may produce cracking, not only in the direction up and down stream, but perhaps along the axis of the dam itself, vertical cracks which in themselves may be very dangerous. Instead of a dam acting as a cantilever sticking up there, it might be acting as a succession of cantilevers, one leaning on the other like a pile of boards, and we might have a collapse.

Now the course of investigation would seem to be, first of all, to find a cement which would not evolve any heat, if such a thing were possible. While that is not possible, we are directed to a desirability of a cement with low heat evolution; perhaps a type of cement different from that we now employ. We have gone to quick-hardening cements, splendid for certain purposes, but generally involving sudden and large evolution of heat. Other things being equal, we would expect the finely ground cement showing more heat evolution. Chemical compositions generally found in our quick hardening portland cements would make for large heat evolutions. Perhaps not even our normal cement which we have been using for years past, is the best cement for dams or other mass concrete construction. We may come to use a cement of relatively low heat evolution—perhaps of coarse grains or high silica content, or the cement manufacturing process may play some part which will give us a low heat evolution—a cement which will gather its strength slowly, the concrete remaining in a semi-plastic condition for a longer time and therefore affording opportunity for adjustment within the mass, as it expands and contracts, so that finally there will not be left within the mass any large residual stresses. That would be a desirable type of cement for mass concrete construction. Instead of having two types of cement, the normal portland cement and quick hardening portland cement, we might have still a third for mass concrete construction—a slow-hardening portland cement of low heat generation. This committee comprises 25 members—a representative group of engineers of considerable prominence in the fields of mass concrete construction and of research. Many

of its members are in our western territory, where they are building most of the large dams, men who have been engaged in dam design and construction, some of them for a good many years, together with some of our eastern men, who are experts in the field of research. The work has been divided among four subcommittees—Laboratory program, Field program, Cement and Admixtures and Executive. The committee has had two meetings at which the cooperation of groups representing projects of large magnitude has been pledged—California's Department of Dams, the U. S. Bureau of Reclamation, the Los Angeles County Flood Control District, and others; and likewise we have the promised cooperation of the manufacturers of cement and admixtures, not only in furnishing materials and personnel for carrying out these tests under centralized administration, but also in the way of actual monetary contributions which are important, gentlemen, in tests of considerable magnitude.

It is all right in our ordinary tests to play with little briquettes, two-by-four or six-by-twelve cylinders, but when you get into mass concrete, gentlemen, it becomes a different story. There you have not only to make observations in the field under field conditions in the actual structures, but you have got to make in your laboratory, specimens of unprecedented size. In the program of tests we have laid out, some of our smallest specimens are cubic yard masses; some of our large specimens contain fifty cubic yards. One test proposed is upon cylinders 12 ft. in diameter by 12 ft. high, in each of them containing approximately 50 cu. yds of concrete. In carrying out this particular test we have not only to manufacture the cylinders but to seal them up in such a manner that they will neither give up nor absorb moisture, and keep them in a special room where the temperature will be constantly maintained outside at the same temperature as that inside the mass and automatically regulated. Inside each of these 12-ft. cylinders, devices will be imbedded for measuring the strains of the mass. Smaller cylinders will be embedded in the large and their properties determined.

We are desirous of securing the cooperation of all those who have anything to do with mass concrete construction, who have not already come forward and volunteered their services.

CONVENTION DISCUSSION

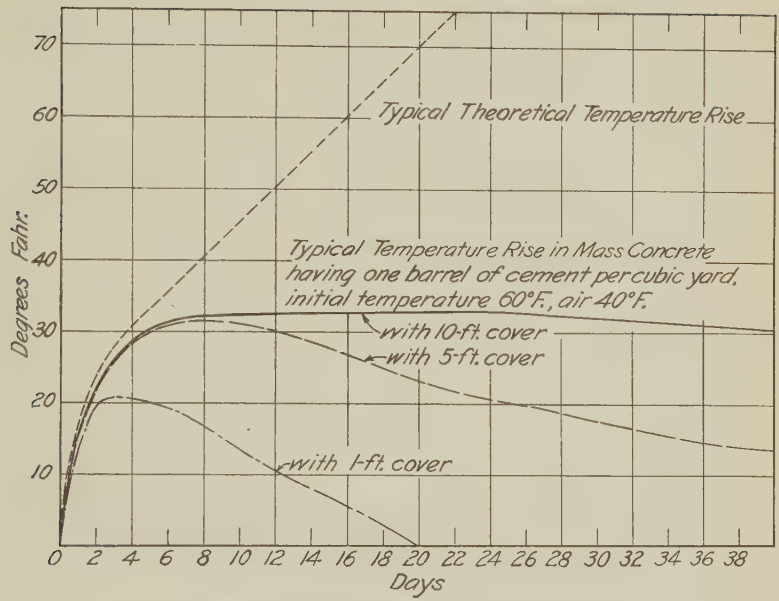
CHAIRMAN HOLLISTER—The subject of mass concrete is assuming at this time particular importance with the impending contracts for the construction of the Hoover Dam. Normally we think of 6,000 yards of concrete as being a fair sized job. One unit of the Hoover Dam itself will take 6,000 yards a day for two years, about three and a half million cubic yards of concrete in the mass of the dam itself, not including minor appurtenances running to over a million yards. The chairman of the committee on Properties of Mass Concrete is a member of the Board of Consulting Engineers on concrete on this dam. The Board consists of five men under the chairmanship of Mr. Bates, all five of them are members of this Institute.

L. G. LENHARDT—Talking about millions of yards of concrete and 6,000 yards a day for two years rather startles me. I have a few data here that I happened to jot down. On a tunnel job—12 ft. diameter and some hundred feet beneath the surface, ground temperature 55 deg.; mix used, approximately 1:2:3; water-cement ratio varied between five and a half and six and a half gallons; temperature of concrete on placement, 65 to 70 deg.; wall thickness 21 in.; temperature of the concrete, four different readings, 118 deg., 122 deg., 123 deg., 125 deg.; maximum at three days after placement. The same temperature held four days and showed slight signs of dropping off at five days. The concrete was placed at the rate of 8 to 10 yds. per hour. On another job, caisson, 8 ft. walls, outside temperature, 18 to 20 deg., concrete placed at 45 deg.; placed at the rate of 32 to 40 cu. yds. per hour with a total of 2,600 cu. yds. in the pour. Pried back face of forms at the end of 24 hours and found a temperature of 80 deg. at the face of the concrete. We had a pipe insert extending four or five inches back in the concrete and the temperature at that point was about 85 deg.

WRITTEN DISCUSSION

BY CLIFFORD BETTS

The summary of existing data on "Properties of Mass Concrete" by Committee 108 logically deals primarily with the chemical generation of heat and resulting expansion and contraction of the mass. This phase of mass concrete behavior merits intensive



study in both the field and laboratory in order that design of large structures may not be handicapped by inadequate data. The committee has performed a distinct service in presenting a summary of research to date and a proposed program of investigations whereby future investigations may be coordinated.

Shrinkage stresses in massive concrete structures—notably dams, piers and arches—may even exceed loading stresses unless heat generation is controlled. Cracking and incipient disintegration, due to unequal contraction after expansion and to too rapid evaporation of uncombined water during early curing periods when excessive temperatures are permitted, demand that consideration be given heat control.

Rapid placing by modern methods lessens the opportunity for heat dissipation and the trend toward high early strength cements helps create a vicious circle wherein the higher temperature caused by the more rapid early chemical action in turn accelerates this action. High temperatures, caused by fine grinding, high lime or alumina content, are more evident in rich mixes and therefore enter into the design.

The heat rise in the average concrete mass will vary from 30 to 70 deg. F., within the first two weeks after placing depending upon the cement content, the thickness of cover and the ambient temperatures. Fig. 1 illustrates a typical temperature rise in mass concrete together with the theoretical rise that might be expected if no heat were lost. The cooling effect of the atmosphere upon concrete having less than ten feet of concrete cover is obvious. High initial heat in the concrete and high atmospheric temperatures raise the peak and decrease the rate of radiation. The behavior of the concrete during the cooling period following the peak temperature is influenced by the deferred hydration of the cement and, where radiation is slow, the return to normal temperature may require several years. An extensive research program disclosing the extent of such chemical action is an immediate need.

Control of heat generation involves mitigation of the causes coupled with engineering design that takes cognizance of the many influencing factors. Reducing the cement content in the mix may cut down the temperature rise as much as 40 per cent

EARLY TEMPERATURE RISE IN MASS CONCRETE

(although such a range is rarely possible in design). Changing cement grinding from 90 to 80 per cent fineness (per cent passing No. 200 sieve) may be made to curtail heat development 20 per cent (usually at the expense of ultimate strength). In manipulating the lime, alumina, magnesia, iron and other constituent parts of the cement to produce a slow setting concrete for mass placing, advantage can be taken of the fund of knowledge acquired in perfecting high early strength cements. The use of precast concrete blocks that can be cured under ideal moisture and temperature conditions and readily handled by cableways, offers a solution of the placing problem which rivals the common expedient of limiting the size of pours so as to facilitate radiation.

Readers are referred to the JOURNAL *for November, 1931, (Vol. 28), for further discussion which may develop. Such discussion should reach the Secretary by October 1, 1931.*

Tentative Specification for Ready-Mixed Concrete

*Report of Committee 504**

MILES N. CLAIR, AUTHOR CHAIRMAN

Committee 504 first presented at the February 1930 meeting a report[1] consisting principally of the work of the author-chairman. The specification included in that report received considerable helpful criticism and discussion. As the result of that discussion, both at the convention and at subsequent meetings of the Committee, a new specification was developed which was presented for your consideration in the November 1930 issue of the Journal. That specification was further modified by the committee at this convention, to meet the objection of some members of the committee and others interested. The specification proposed by this committee is in five sections. The first, General, logically deals with the limitation of the specification, definitions that are necessary for its understanding, and a general requirement in regard to the operation of the plant. The second deals with materials and refers generally to the usual specifications for materials. There is nothing startling nor unusual in either the first or second sections. The third section refers to concrete quality and proportioning, and this section is divided into five parts. Article A deals with concrete quality and proportioning generally, stating that they shall be in accord with the general specifications for concrete, plain and reinforced, but there is a modifying statement that the proportions may be changed at the discretion of the architect or engineer. The reason is that in the use of ready

*This report was presented by Mr. Clair at the 27th Annual Convention Milwaukee, February 24-26 1931, introducing the committee's recommendations for revision and tentative adoption of the specification published November, 1930; *Proceedings*, Vol. 27, p. 281. As amended and tentatively adopted by the convention, the specification follows Mr. Clair's introduction.—Editor.

[1]A. C I Journal, February, 1930; *Proceedings*, Vol. 26, p. 467.

mixed concrete, it is frequently necessary to make changes that might not be contemplated or necessary under the general specification. Article B deals with the measurements of the concrete aggregates and the cement by weight—by weight because of the necessity for ready handling of varied proportions. Central mixing or truck mixing plant operations must deal with different proportions at almost a moment's notice. However, we were faced with the fact that some operations use bag cement, so a footnote allows the use of bag measurements if you do not split bags. You can thus safeguard more or less the accuracy of your measurements, which brings it all back practically to a weight basis. The measurement of water may be by weight or by volume; that is in accordance with the usual practice. The volume of concrete produced by the batch shall be taken as the same absolute volume of the ingredients. That statement should appear in this specification, we feel, because it is frequently a matter of controversy, and it might as well be made definite. I think there is very little difference of opinion among engineers as to how the concrete should be measured, but there seems to be a good deal of difference among contractors. The next item deals with requirements for a statement of control quantities. The engineer wants to know what goes into every load of concrete, and so he should have a statement with each load as to what does go in. The next item requires that facilities be provided at the plant to enable the architect or the engineer to check at any time the quality of the materials and the accuracy of the measurements. That is just the same way as we have it at a steel plant. They have facilities at a steel plant so you can check up on the quality of the steel. The requirements for tests are the same as in the general specification. You will recall in the original specification the requirements as to tests were more stringent, but discussion has finally resulted in the requirement that they be no more stringent than required by the general specification. Section four deals with mixing and transporting concrete. This is the item which gave rise to the most discussion, because it is here that ready-mixed concrete differs most from ordinary concrete. I think however when we consider this item of the specification, we should keep in mind that we have been doing essentially the job of the ready-mixed concrete operation for many years on

our large jobs—large dam jobs and large road jobs. If that is kept in mind, we will not be so concerned about some of the limitations. We want trucks that do not lose any of the ingredients. Second, the concrete mixer shall be of the revolving type of mixer, whether operating on the truck or at a fixed point. We do not want to go through again, at this time, the evolution of the mixer so we are requiring that it be a revolving drum type of mixer. The committee felt that the limitations on the number of revolutions and the time of mixing, the capacity, that is, the load put into the mixer, should be in accordance with the manufacturers' rating and recommendation. That of course some day may be changed. Paragraph 3 of Article A, has involved considerable discussion. As originally written in the specification published last November it read:

(3) A maximum period of .... hours may elapse between the addition of the cement to the aggregates and the placement of the concrete in the forms; but the concrete as placed shall be of the consistency and workability required by the General Specification for Plain and Reinforced Concrete.

The committee, on reconsideration, felt that the emphasis was wrong and amended the paragraph to read as follows:

(3) The concrete as placed shall be of the consistency, workability, materials and water contents as required by the General Specification for Plain and Reinforced Concrete. In no case, however, shall the time elapsing between the addition of the cement to the aggregate and the placement of the concrete in the forms be more than .... hours[5] without special permission from the architect or engineer.

A footnote to this section is likewise modified. The original footnote read as follows:

The architect or engineer must indicate the limiting period. A maximum period of one hour is recommended.

The committee has voted that this footnote also be amended, to read as follows:

The Architect or Engineer must indicate the limiting period. An elapsed time of one hour has been found satisfactory under the usual operating conditions, but the permissible time may be longer under special conditions as determined by the workability and methods of placing.

A fourth item, is usual, that concrete shall not be retempered nor partially hardened concrete be placed in the structure. The fifth item requires precautions for the protection of concrete in transport when necessary.

Section B, Under Mixing and Transporting, deals with central plant-mixed concrete, provides that the concrete shall be mixed in accordance with the general specifications before being placed in transporting vehicle. In other words, you are not to count on the agitating effect of the usual agitating or non-agitating type of vehicle as being effective. The type of truck is limited to three classes—non-agitating, which is limited by the consistency of the concrete; the re-mixing type and the agitating type. The footnote under this section originally read:

> The Architect or Engineer must indicate the limiting slump. A maximum allowable slump of two and a half inches for non-agitating type truck and six inches for remixing type truck is recommended.

We felt that this, again, did not properly place the emphasis and the committee amended it to read as follows:

> The Architect or Engineer must indicate the limiting slump. An allowable slump of two and a half inches for non-agitating type trucks and six inches for remixing type trucks has been found satisfactory under usual operating conditions, but the use of greater slumps is permissible, if it can be shown by test that the concrete can be delivered without segregation.

That, incidentally is the second point concerning which there was the most discussion. The remaining part of the specification received much better treatment. Section C, dealing with Central Plant-Proportioned Truck Mixed Concrete included a precautionary paragraph that the procedure in loading the truck mixer shall be such that the cement and aggregate are uniformly distributed throughout the truck when the loading is completed. There is a requirement that the truck be so equipped that the amount of water added and the time of agitation or the number of revolutions during the transportation can be verified.

The fifth section of the specification deals with the requirement on delivery. The first provision is that the organization supplying concrete shall have sufficient plant capacity and transportation apparatus to insure continuous delivery at the rate desired; the second recommends that the interval between loads shall not exceed thirty minutes, or in any case be so great as to allow the concrete in place to become partially hardened; and third, that the method of delivering the concrete shall be such as will facilitate placing with the minimum of re-handling and without damage to the structure or concrete.

The committee has given considerable time to this specification; and has tried to lend a receptive ear to all suggestions. One suggestion only was received from outside the committee previous to today, since the publication of the specification in November. We feel it is worthy of acceptance as a tentative specification of the Society, although we recognize that the practice in this field is moving very rapidly and that modifications may be desirable before it is moved to a standard. I move, on behalf of Committee 504, the tentative adoption of the specification published in the November 1930 JOURNAL of this Institute, as here amended. (The specification as amended and tentatively adopted follows:)

TENTATIVE SPECIFICATION FOR READY-MIXED CONCRETE

*American Concrete Institute Tentative Specification 504-31-T**

MILES N. CLAIR, AUTHOR-CHAIRMAN

Committee 504, Specifications for Ready Mixed Concrete

1. GENERAL

(A) These specifications cover the special conditions affecting the use of Ready-Mixed Concrete and supplement the requirements of the General Specifications for Plain and Reinforced Concrete for this Contract.

(B) The term "Ready-Mixed Concrete" is used in these specifications as meaning[1] Central Plant-Mixed concrete and Central Plant-Proportioned Truck-Mixed concrete.

(C) The place where the materials are proportioned is referred to in these specifications as "the plant."

(D) The operation of the plant shall be under the direct supervision of a competent engineer.

2. MATERIALS

(A) All aggregates, cement and water shall be of the quality required by the General Specifications for Plain and Reinforced Concrete. All conveyors, bins and hoppers shall be cleaned of unapproved materials before starting to manufacture concrete for this contract.

---

*Proposed by Committee 504, November, 1930, JOURNAL, p. 281, and now published with amendments adopted by the 27th Annual Convention, February, 1931.

[1]The Architect or Engineer must indicate which systems are allowed. It is recommended that in general both be included.

(B) No change shall be made in the materials used, during the course of this contract, except with the permission of the Architect or Engineer.[2]

3. CONCRETE QUALITY AND PROPORTIONING

(A) The concrete quality and proportions shall be in accordance with the requirements of the General Specifications for Plain and Reinforced Concrete. Proportions, however, shall be subject to change under the direction of the Architect or Engineer when necessary to produce proper workability or satisfactory strength.

(B) The measurement of the concrete aggregates and the cement[3] shall be by weight so that the proportions can be readily adjusted to assure a definite volume of concrete of the quality specified. The measurement of the water may be by weight or volume. The volume of concrete produced per batch shall be taken as the sum of the absolute volumes of the ingredients.

(C) A statement of the control quantities[4] used and the time at which the vehicle was loaded shall accompany each load of concrete. The organization supplying the ready-mixed concrete shall have available sufficient test data, certified by a competent concrete testing engineer, to enable the Architect or Engineer to determine whether the quantities used will give concrete of the desired quality and the stated quantity per batch.

(D) Facilities shall be provided at the plant to enable the Architect or Engineer to check easily at any time the quality of the materials and the accuracy of the measurements.

(E) Tests of the concrete as delivered to the forms shall be made during the progress of the work as required by the General Specifications for Plain and Reinforced Concrete.

4. MIXING AND TRANSPORTING CONCRETE

(A) *General*

(1) Transporting vehicles shall be so constructed as to insure rapid delivery without loss of ingredients.

(2) All concrete shall be mixed in a revolving drum type of mixer, whether stationary or movable. The mixing time or

[2]In the use of this specification for a particular project one of these must be stricken out throughout the text to avoid conflict.

[3]Bag measurement may be used provided the batches do not involve fractions of bags.

[4]"Control quantities" refers to the requirements of the specifications such as water-cement ratio, cement content, or proportions.

number of revolutions shall be as recommended by the manufacturer; but shall not be less than required by the General Specifications for Plain and Reinforced Concrete. The mixer shall not be loaded beyond the capacity recommended by the manufacturer.

(3) The concrete as placed shall be of the consistency, workability, materials and water contents as required by the General Specifications for Plain and Reinforced Concrete. In no case, however, shall the time elapsing between the addition of the cement to the aggregate and the placement of the concrete in the forms be more than 00 hours[5] without special permission from the Architect or Engineer.

(4) Under no circumstances shall partially hardened or retempered concrete be placed in the structure.

(5) Special precautions shall be taken to protect the materials from damage during transportation under extreme weather conditions.

(B) *Central Plant-Mixed Concrete*

(1) The Concrete shall be properly mixed in accordance with the requirements of the General Specifications for Plain and Reinforced Concrete before being loaded into the transporting vehicle.

(2) Non-agitating type transporting vehicles shall not be used to transport Central Plant-Mixed concrete when the consistency of the concrete is wetter than a —-inch slump.[6]

(3) Remixing type transporting vehicles[7] shall not be used to transport Central Plant-Mixed concrete when the consistency of the concrete is wetter than a —-inch slump.[6]

(4) Agitating type transporting vehicles may be used without restriction as to consistency.

(C) *Central Plant-Proportioned Truck-Mixed Concrete*

(1) The procedure in loading the truck mixer[8] shall be such

[5]The Architect or Engineer must indicate the limiting period. An interval of one hour has been found satisfactory under the usual operating conditions, but the permissible time may be longer under special conditions as determined by the workability and methods of placing.

[6]The Architect or Engineer must indicate the limiting slump. An allowable slump of two and a half inches for non-agitating type trucks and six inches for re-mixing type trucks has been found satisfactory under usual operating conditions, but the use of greater slumps is permissible, if it can be shown by tests that the concrete can be delivered without segregation.

[7]Re-mixing vehicles are those provided with special means of remixing or agitating the concrete to some degree during discharge but not during transportation.

[8]It is suggested that the cement and aggregates be fed simultaneously into the end loading type of truck mixer. For the top loading type of mixer this method of charging is not so essential; but is also recommended.

that the cement and aggregates are uniformly distributed throughout the batch when the loading is completed.

(2) Where the concrete is mixed during transportation of the batch to the job, means shall be provided so that the mixing time and the quantity of water added can be readily verified by the Architect or Engineer.

5. DELIVERY

(A) The organization supplying concrete shall have sufficient plant capacity and transporting apparatus to insure continuous delivery at the rate required.

(B) The interval between loads shall not exceed — minutes,[9] or in any case be so great as to allow the concrete in place to become partially hardened.

(C) The methods of delivering the concrete shall be such as will facilitate placing with the minimum of re-handling and without damage to the structure or concrete.

[9]The Architect or Engineer must indicate the interval allowed. A maximum of thirty minutes is recommended.

Tentative Construction Specification for Concrete Work on Ordinary Buildings (502-31-T)

*Report of Committee 502**

ARTHUR R. LORD, AUTHOR-CHAIRMAN

The report of Committee 502 was published in the Journal for November, 1929.[1] Discussions (published in March, 1930,[2]) prompted the Committee to make several revisions designed to cover all valid objections. As thus amended, by the Committee, the specification was tentatively adopted by the Institute by vote of the Convention at New Orleans a year ago.

In the early discussion the rather severe treatment accorded admixtures in this proposed standard went unchallenged. As time went on, however, I understand that this report began to cause the "Admixture Boys" (I borrow this convenient term from the discussion of one of them) some embarrassment. In considering their distress it is but fair to remember that the subject of admixtures has caused the Advisory Committee embarrassment also. Our long projected committee to report on admixtures has been the most difficult committee we have had to deal with in recent years. Only after long search and several tumbles have we found a man to head this committee who possessed the necessary freedom from prejudice, reputation for fairness and scientific accuracy, together with sufficient backbone to deal firmly with such experienced and persuasive gentlemen as the "Admixture Boys."

That was the situation when the Program Committee put this committee report on for discussion, with the committee proposing to ask that the tentative specification be sent to letter ballot for

*This report was presented by Mr. Lord at the 27th Annual Convention, Milwaukee, February 24-26, 1931.

[1]A. C. I. *Proceedings*, Vol. 26, p. 1.

[2]A. C. I. *Proceedings*, Vol. 26, p. 580.

adoption as a full standard. Since its tentative adoption three discussions brought up for the first time, the subject of the highly obnoxious Article 10. These discussions were published in the JOURNAL of September, 1930.[3] Fortified by an excellent dinner, stimulated by the hearty fellowship of last evening, the "Admixture Boys" decided to confer rather than to dance. Having reached without difficulty the unanimous conclusion that Article 10 was hostile and that something should be done about it at the eleventh hour, I was sent for. My personal safety was assured by the presence of Mr. Goldbeck as arbitrator, and I am pleased to recommend him for that service should any other group stand in a similar need.

I have never before seen so many admixture representatives peaceably assembled. If Article 10 serves no more useful purpose than to bring the representatives of all admixture manufacturers to a realization that their interests are mutual rather than opposing, that the very information that Committee 502 demands for the safe guidance of the users of admixtures is the thing most helpful to the admixture business, its brief existence will have been worth while. The meeting gave a free and full opportunity for frank discussion of the attitude of this committee—in which it is no less unanimous than the admixture representatives—towards this subject. After a few hours of friendly and hearty debate we all went into a huddle with the referee and as a result I am privileged to submit the "Goldbeck formula" for the consideration of the convention at this time.

The Goldbeck solution strikes out the first two paragraphs of the present Article 10 and substitutes one new paragraph.

Article 10 in the original publication of the proposed specification follows:

10. ADMIXTURES AND SPECIAL CEMENTS.

Nothing shall be added to the essential ingredients of concrete (portland cement, fine and coarse aggregate, and water) without the approval of the Architect or Engineer in writing and then only such materials shall be added as have been thoroughly tested by reputable independent investigators so as to demonstrate their effect on the strength, elastic properties, permeability and permanence of concrete produced from materials such as are being used on this work.

[3] A. C. I. *Proceedings*, Vol. 27, p. 99.

No special cement shall be used in place of standard portland cement except upon the same basis of adequate test and known effect upon all vital properties of the resulting concrete.

Whenever such admixtures or special cements are approved for use on this work in this manner they shall be used in accordance with the manufacturer's instructions and in conformity with their use in the tests on which their acceptance is based.

The paragraph which it is now proposed to substitute for the first two quoted above, follows:

Materials proposed for use in concrete in addition to the essential ingredients (portland cement, fine and coarse aggregate and water), or special cements proposed for use in place of standard portland cement, shall be permitted only with the approval of the Architect or Engineer in writing, on the basis of acceptable tests to demonstrate thoroughly the effect of such materials on the strength, elastic properties, permeability and permanence of the concrete.

The final paragraph of Article 10 is to stand.

The committee also wishes to make another change in this specification, designed to permit the use of cement in bulk as follows: At the end of the first sentence of the second paragraph of Article 5 add a new clause reading:

. . . except that cement may be shipped in bulk direct from manufacturers storage to this work, or to the central mixing plant where the concrete for this work is proportioned.

With these two changes I move you, Mr. Chairman, that tentative specification 502-30-T be approved as amended and be continued as a tentative specification of this Institute—502-31-T. While no arrangement was made to this effect last night—this morning, rather—I trust that some admixture representative will be gracious enough to second my motion.

He was, and the motion was carried without dissent.

Tentative Construction Specification for Concrete Work on the Small Job (506-31-T)

Report of Committee 506

ARTHUR R. LORD, AUTHOR-CHAIRMAN

Arthur R. Lord, author-chairman Committee 506, proposed, at the 27th Annual Convention, February 24-26, 1931, amendments to Articles 4 and 10 of Proposed Construction Specification for Concrete Work on the Small Job—first published as a report of the Committee in this Journal, September, 1930,[1] and discussed January, 1931.[2]

Article 4 in its original form and as amended is shown in the following—the words underlined to be deleted and italic indicating new wording:

4. Concrete materials

Portland cement shall be used for all concrete work. This cement shall be certified by the dealer to comply with all requirements of the standard specifications of the American Society for Testing Materials. (Serial designation: C9-26, or latest standard of this Society.)

Aggregate for this work shall be certified by the dealer (See Note 1 opposite)* to comply with the following specifications:

Fine aggregate for this work shall consist of well graded natural or artificial sand, or other approved inert materials with similar characteristics, taken from sources that have furnished satisfactory materials for previous concrete work for several years, or if from a new source shall be thoroughly tested for soundness and permanence. It shall comply with the provisions of the Tentative Purchase Specifications for Concrete Aggregates, E5-A-26T, *E5-A-29T*, (or latest standard of the Institute) of the American Concrete Institute. In applying these provisions the sieve analysis of dried aggregate shall show as follows:

Passing No. 4 sieve—not less than 85 per cent.

Passing No. 50 sieve—between 5 and 30 per cent. (Note 2 opposite.)

*References (see note opposite) are to the original printing of the specification where the "whys" of the provisions are discussed—Editor.

[1]A. C. I. *Proceedings*, Vol. 27, p. 65.

[2]A. C. I. *Proceedings*, Vol. 27, p. 525.

Passing No. 100 sieve—not more than 5 per cent.

Fineness Modulus—not less than 2.50

and the weight of clay and silt removed by decantation shall not exceed 3 per cent.

Coarse aggregate for this work shall consist of crushed stone, gravel, air-cooled blast-furnace slag, or other approved inert materials of similar characteristics, taken from sources that have furnished satisfactory materials for previous concrete work for several years or if from a new source shall be thoroughly tested for soundness and permanence. It shall comply with the provisions of the Tentative Purchase Specifications for Concrete Aggregates, E5-A-26-T *E5-A-29-T* (or latest standard of the Institute) of the American Concrete Institute. *The maximum size of the coarse aggregate shall be one inch unless the use of a larger maximum size is directed by the Architect or Engineer.* In applying these provisions the sieve analysis of dried aggregate shall show as follows:

Passing 1-inch sieve—not less than 95 per cent.

Passing No. 4 sieve—not more than 10 per cent.

Passing No. 8 sieve—not more than 5 per cent.

Fineness Modulus—between 6.30 and 7.50.

The weight of slag shall not be less than 65 lb. per cu. ft. The weight of soft, friable, thin, elongated or laminated pieces shall not exceed 3 per cent.

Aggregates shall be so stored and handled at all times as to remain separate from each other and free of all foreign material until placed in the mixer. (See Note 5.) Drainage shall be provided where necessary to avoid accumulation of water in aggregates.

Water shall be taken from the usual drinking supply and shall be paid for by this Contractor.

The same materials shall be used throughout the work, including the same brand of Portland Cement from the same mill, the same sand and gravel or crushed rock from the same source and from the same bin at the screening plant. (See Note 3.) This Contractor shall be fully responsible for the correct certification of all materials by the material dealer, as provided above. In case of doubt this Contractor shall pay for the necessary tests to be made under the direction of the Architect or Engineer.

To Article 10: "Measurement of the Batch" a new paragraph is added as follows:

When the concrete mix is determined by means of preliminary tests made by an approved laboratory and using the same materials as are to be used in the work, the water-cement ratio to be used in the work shall be taken as that giving a strength under standard laboratory conditions, at the age at which the concrete is to be put into service, not less than fifteen per cent greater than the ultimate strength required of the concrete in the work.

Both these amendments were accepted by the Convention and as thus amended the specification was tentatively adopted.

Tentative Specification for Supplying, Fabricating and Setting Reinforcing Steel on Ordinary Buildings (503-31-T)

Report of Committee 503

W. F. ZABRISKIE, AUTHOR-CHAIRMAN

The report of this committee published in this Journal, February, 1930;[1] formally presented at the 26th Annual Convention, New Orleans, February, 1930, and discussion published in this Journal, June, 1930,[2] was presented to the 27th Annual Convention, Milwaukee, February, 1931, for tentative adoption of the Proposed "Specification for Supplying, Fabricating and Setting Reinforcing Steel on Ordinary Buildings" with an appendix: "A Steel Setters Primer," motion by Mr. Zabriskie was seconded and adopted. The document now takes the serial designation as a tentative specification "503-31-T."

Concreting the Calderwood Tunnel*

BY W. R. JOHNSON†

THE PROJECT

The Calderwood hydro-electric-development, one of the projects of the Aluminium Company of America, is on the Little Tennessee river, approximately a mile above Calderwood, Tennessee.

The development consists of a 230-ft. thin-section-arch overflow dam, with a 40-ft. gravity dam several hundred feet below, built to form a pool to cushion the overflow from the main dam; a 26-ft. pressure tunnel 2400 ft. long and the power house. Two 56,000 h. p. turbines are installed to operate under a head of 213 ft. Fig. 1 shows the general layout of the development.

As this report deals primarily with the concreting of the tunnel only a brief description will be given of the operations leading up to this work.

The entire length of the tunnel including penstocks is approximately 2400 ft. It is circular for the first 219 ft. from the intake, with a diameter of 26 ft. 6 in. inside the 12-in. concrete lining. The first 131 ft. of this section is level and the remaining 88 ft. slopes downward at an angle of 51 deg. with the horizontal. The next section, 1727 ft. 6 in. slopes downward on a 2 per cent grade. This section is 26 ft. wide, with 11-ft. vertical side walls and a semi-circular crown of 13 ft. radius. The last 400 ft. branches out into three 16-ft. steel penstocks which slope steeply downward into the power house.

The entire tunnel was driven or excavated from an adit at the lower end of the tunnel. This adit is not a part of the permanent

*Presented by title (in author's absence) at 27th Annual Convention, Milwaukee, Feb. 24-26, 1931.

†Concrete Technician, Calderwood Development, of the Aluminum Company of America.

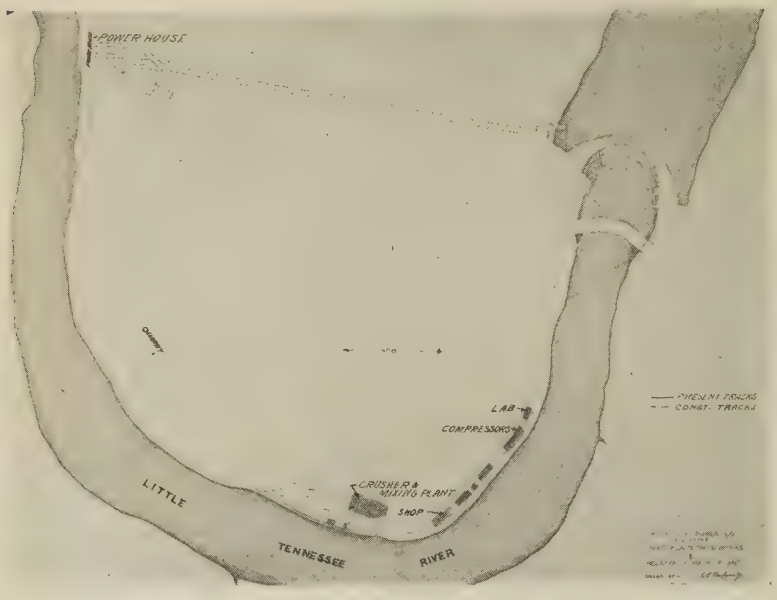

FIG. 1—GENERAL LAYOUT CALDERWOOD HYDRO-ELECTRIC DEVELOPMENT ON LITTLE TENNESSEE RIVER

tunnel and intercepts penstock No. 3 at the level of the main tunnel.

An 11 by 11-ft. heading was driven the entire length of the tunnel and later enlarged to full size by drilling and shooting. During the driving of the heading the muck was handled by an electric mucking machine (Fig. 4) and loaded into 2-ft. gage cars handled by storage battery locomotives. In the enlarging operations the muck was loaded into standard gage 6-yd. cars by a 1¼-yd. air shovel and removed by a gasoline-electric locomotive. The muck was later sent to the crushing plant and made into concrete aggregate, for use in the tunnel or dam as required. The dimensions of the tunnel are shown on Fig. 1 and 5.

All concrete was mixed at a plant located about ½ mile from the tunnel adit and transported to the tunnel in 2-cu. yd. sloping side buckets loaded on flat cars pulled by 20 ton "dinky" steam locomotives. The mixing plant was equipped with a 2-cu. yd. Smith tilting (56S) mixer.

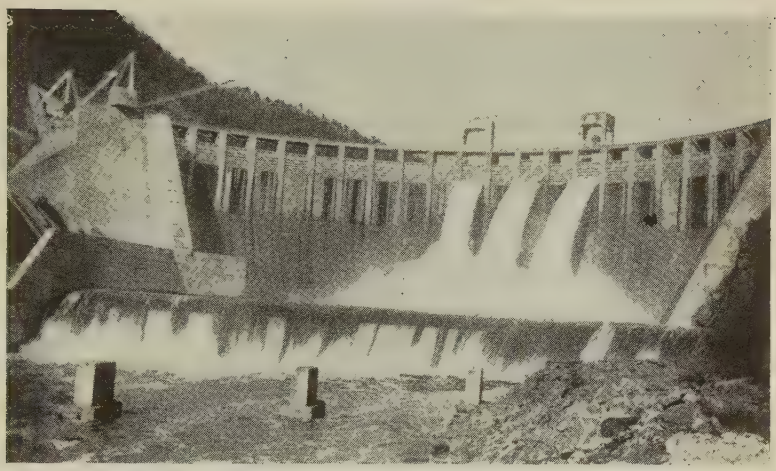

FIG. 2—CALDERWOOD DAM

CONCRETE MATERIALS AND TESTS

In addition to that obtained from excavations for the dam and tunnel, the aggregate used was taken from a quarry about 300 yds. from the crusher and mixer plant. This material was hard, dense arkose and made excellent aggregate. The coarse aggregate was graded from ¾ in. to 3 in. while the fine aggregate was manufactured and produced from the same material and graded from 0 to No. 4. Previous tests and experiments had shown that the elimination of material under ¾ in. in the coarse aggregate prevented raveling and separation of sizes in the bins, thus giving a more uniform product when but one bin was used for coarse aggregate.

The concrete for the entire Calderwood project was designed to produce a compressive strength of 3000 lb. per sq. in. at 28 days when tested as an 8 by 16-in. cylinder. All aggregate larger than 2 in. was removed from the concrete by hand picking at the time the specimens were molded. It was found, however, that a number of the cylinders could not be broken in the 200,000-lb. Olsen hydraulic testing machine, as the strength went beyond the capacity of the machine (4000 lbs. per sq. in. for an 8 by 16-in. cylinder). These strengths were being obtained from concrete placed in the main dam and with a cement content of 4½ bags

per cu. yd., which was considered the minimum that could be used to obtain the desired durability and water tightness in the structure of this type. The size of the test specimens was therefore reduced to a 6 by 12-in. cylinder with all aggregate larger

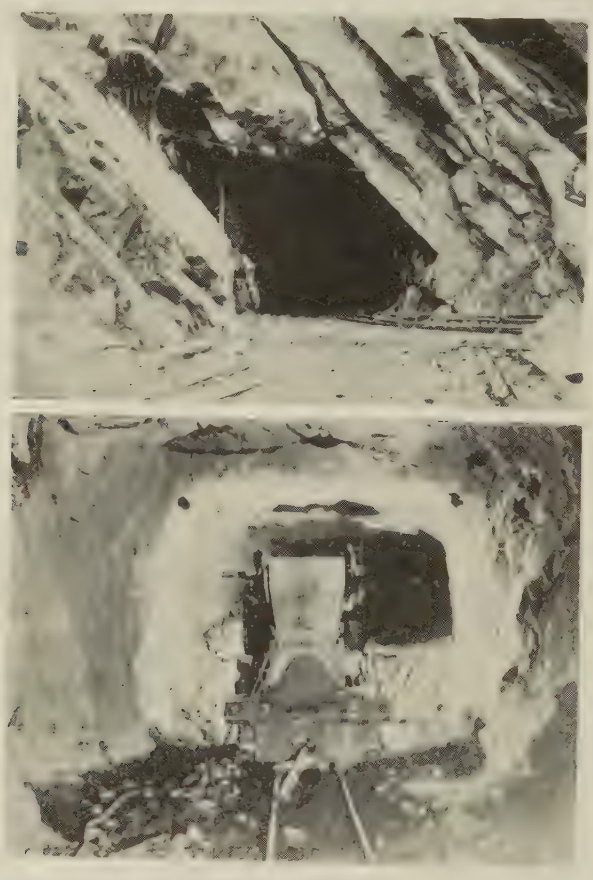

FIG. 3—TUNNEL CONSTRUCTION ADIT
FIG. 4—MUCKING MACHINE IN 11 BY 11 FT. HEADING

than 1½ in. removed from the concrete. Comparative tests showed that the 6 by 12-in. specimens gave strengths equal to 108 per cent of the strengths obtained from 8 by 16-in. specimens molded from the same batch. The average water-cement ratio

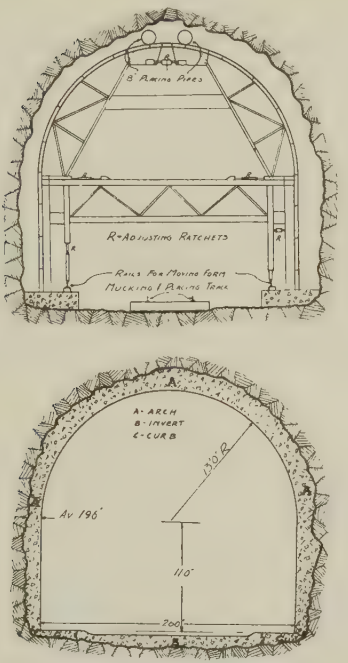

FIG. 5—MAIN TUNNEL SECTIONS, UPPER SECTION SHOWING STEEL FORMS

used for the concrete placed in the main dam was .95 (7.0 gal.), which gave an average strength of 4000 lb. per sq. in. at 28 days. For the tunnel concrete this water ratio was reduced slightly (.90) in order to give a greater factor of safety upon removal of forms 11 to 15 hours after placing. Preliminary tests made with 8 by 16-in. cylinders broken at the age of 14 hours indicated that a water-cement ratio of .90 (6¾ gal.) would give sufficient strength to move the 30-ft. Blaw Knox steel form without danger of any caving in the arch section. In actual practice the form was successfully moved several times, 11 hours after placing the concrete.

PLACING OPERATIONS

The total concrete placed in the entire tunnel, which included intake, main tunnel, and surge shaft, was 28,000 cu. yd. About 85 per cent of this yardage was placed with pneumatic placers.

FIG. 6—ELECTRIC VIBRATOR
FIG. 7—CONCRETE HOPPERS AND PNEUMATIC PLACERS

In general, three separate placing operations were used in the main tunnel. In order of procedure they were: curb, arch, and invert. The concrete sections of the 16-ft. circular penstocks were placed in two operations, bottom segment and main segment, or sides and top. Wooden forms, built in place, were used. The incline section of the main tunnel, which was circular, having a diameter of 26 ft. 6 in., was placed in the same manner as the penstocks. The surge shaft, which had a diameter of 18 ft. and an angle of 51 deg. with the horizontal, was placed in one operation, using collapsible, movable, wooden forms.

In the concreting of the main tunnel flat cars of standard gauge, mounting specially designed hoppers, were used for hauling material from the construction adit or portal into the tunnel. Each car was equipped with four hoppers (Fig. 7), each hopper having a capacity of two cubic yards and arranged so that concrete could be dumped simultaneously from both sides of the car into the curb forms or pneumatic guns, as the case might be.

The placing of the concrete in the main section was started at the foot of the riser, upstream, and progressed down hill on a 2 per cent grade. The curb (Fig. 5) for the entire length of the tunnel was placed first and later used as a foundation for moving and setting the 30-ft. collapsible Blaw Knox steel form used in concreting the arch section. The invert, or tunnel floor, was placed with one pneumatic gun, the operations following 60 to 90 ft. behind the arch placement.

Main Tunnel

Curb—The foundation or bottom was thoroughly cleaned of all muck and washed with a hose. The hopper cars, pulled by a gas electric locomotive, then brought the concrete from the tunnel portal to the forms where it was allowed to flow by gravity from the bottom gate of the hopper through a short, movable chute into the forms where it was spaded into place. Two sections of curb, one on each side of the tunnel, were placed simultaneously.

Arch—The average cycle of operations for concreting of a 30-ft. section of arch was as follows:

1. Moving and setting forms, 3 hours.
2. Placing concrete, 6 hours.
3. Setting and hardening of concrete, 15 hours.

This schedule was adhered to as closely as possible. Delays of different types, such as breakdowns of pneumatic guns, derailment of hopper cars, placing pipe troubles, etc., prevented placing every day. The average loss of time due to these troubles, however, was only about one day every two weeks. The first section of arch placed required 36 hours. Within 10 days this time had been cut down to 6 hours, which was the average time required for placing, although several sections were placed in less than 5 hours.

(LOWER) RANSOME PNEUMATIC PLACER

Fig. 8 shows the set-up used for placing concrete in the arch. The procedure in filling the forms was as follows:

The concrete was brought from the construction adit to the form in hopper cars drawn by a gas-electric locomotive. From the hopper it was fed by gravity through the gates at the bottom into the two pneumatic concrete placers, one on each side of the car. These placers had a capacity of 14 cu. ft., and were of the horizontal type. The placers operated as follows:

The concrete entered the guns (Fig. 8) through a sliding door controlled by compressed air and at the back end and on top of the cylindrical barrel. From here it was forced by a screw feed, operated intermittently, away from the sliding door toward the front end of the barrel until the gun was fully charged. The sliding door was then closed and the screw feed and the air turned on. This action forced the concrete into the 8-in. discharge pipe through which it was forced by the air to its final place of deposit in the forms.

Attached to the forms with clamps were two electric tampers (Fig. 6), one on either side. These were run intermittently during the placing operations and were, no doubt, responsible to some extent for the smooth surface obtained.

In some of the first placements difficulty was experienced with honeycomb occurring in the lower corners next to the previous day's pour. This was caused by segregation in the delivery pipe during the blowing operation. The separation was such that the coarse aggregate was always delivered ahead of the mortar to an extent depending on the plasticity or workability of the mix.

To overcome this difficulty a batch of stiff mortar was first "shot" into each of the lower corners. This was followed by concrete in which the amount of coarse aggregate had been considerably reduced. About the first 15 per cent of the form was placed in this manner, after which the stone content of the concrete was brought back to normal. Very little honeycomb occurred after this method was adopted.

The two major problems encountered in the concreting operations were placing pipe breakdowns and improper consistency of the concrete. The second condition was in most cases the result of the first. The majority of the pipe troubles occurred at the elbows or bends, and the replacements of these sections occurred frequently. The first bends used were made of extra-heavy steel pipe. At the upper elbow, next to the form (Fig. 8), this type of bend was not good for placing more than 150 cu. yds. of concrete. The lower bends, next to the gun, lasted considerably longer. The second type tried was a Hagen-White iron elbow with reversible back. This elbow was a great deal more successful, and, by reversing the back, was good for placing approximately 600 cu. yds. of concrete, after which the backs were replaced.

Trouble was also encountered with pipe flanges, three different types being used before finding one that was satisfactory. These flanges and the order in which they were tried follow: cast-iron, ferro-steel, and steel.

The ends of the discharge pipes were equipped with 22½ deg. extra-heavy steel bends. Frequent patching was necessary to keep these in shape. Some 45 deg. bends were tried and also some

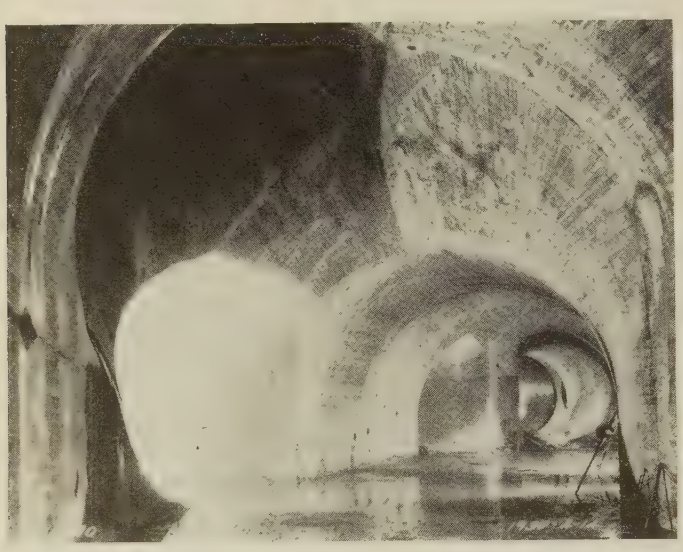

FIG. 9—MANIFOLD SECTION OF TUNNEL SHOWING ENTRANCES TO PENSTOCKS AND SURGE SHAFTS

straight sections. The most satisfactory position for the ends of the discharge pipe at the beginning of a pour was 5 to 6 ft. from the back of the bulkhead. After the form was one third to one half full, however, the position of the end of the discharge pipe or whether it was equipped with a bend or was straight did not seem to matter, equally good results being obtained with the end of the pipe placed 20 ft. from the bulkhead.

The consistency or workability of the concrete was one of the controlling factors in the placing operations, and great care was exercised to keep it correct in order to avoid delays in placing, as well as to prevent honeycomb in the finished job.

For proper placing, it was found that the concrete should be neither too wet nor too dry. A mix that was too wet would segregate badly during placing operations, while one that was too dry could be removed from the hoppers only with great difficulty. The ideal mix for pneumatic placing with materials used on this job was one that gave a slump of 4 to 5 in. with approximately a 1:2:3 mix and which did not segregate upon

being removed from the hopper cars. A mix of this type would "shoot" with great ease and segregate but little in the form.

As short a delay as 15 minutes at the placers during concreting operations would be sufficient to upset the entire cycle of operations, so that the ultimate delay might easily total an hour or an hour and a half before all of the setting concrete could be removed from the loaded hopper cars and buckets. Having no means with which to keep the concrete in the buckets or hoppers agitated when allowed to stand for 30 minutes or more, great difficulty was experienced in removing it, especially from the hoppers, after this time. To prevent delays of this type as much as possible, the inspector kept in constant touch with the mixer plant and the transfer operations at the tunnel entrance. No concrete was transferred from the buckets to the hopper cars if a breakdown occurred, and if the delay amounted to more than 30 minutes, the material was sent to the dam where it could be easily placed in the open forms by means of the electric tampers used in this work.

Invert—After thoroughly cleaning the invert, or bottom, of all muck and dirt, and washing with a hose, the concrete was brought in a hopper car to the placer on the right hand side of the tunnel. From here it was blown through an 8-in. pipe, 100 to 125 ft. long, into the invert form which was a great deal like a small section of pavement slab. A small wooden bulkhead, or stop, was used at the discharge end of the placing pipe to prevent the concrete from scattering unduly. From this point the material was shoveled into place and brought to grade by means of a screed, after which the surface was finished by means of a wooden float.

While this method of placing produced some surface laitance, due to the wet mix necessarily used with the pneumatic placers, it was decidedly the most economical process. The set-up was the same as that used in placing the arch section with the exception of one or two small changes in pipe connections. The work was done at night, thus not interfering in any way with the placing of the arch section.

With the small temperature changes encountered in a tunnel of this type, with no alternate freezing and thawing, and with

practically no abrasive or wearing action due to the slowly moving water, the writer does not believe that scaling on account of this laitance will be particularly detrimental to the concrete lining.

FIG. 10—MAIN TUNNEL

Penstocks and Riser

The same general procedure was used for concreting the riser and penstocks as was used in the main tunnel, with the exception that the forms were wood, built in place. Due to the small size of the penstocks, but one placer was used. This made it necessary to shift the end of the delivery pipe from one side to the other. Vibrators were not used, the concrete being booted and tramped into place.

Surge Shaft

The two-yard buckets of concrete were removed from the train and dumped into a hopper mounted on a platform at the foot of the mountain in which the surge chamber and shaft were located. From here it flowed by gravity into a second hopper mounted on a specially built car which was then pulled by cable, powered from the unloading derrick, approximately 250 ft. up a steeply inclined narrow gauge track to a third hopper on the mountain side. After being dumped into this hopper, the concrete flowed through a short chute into an upright pneumatic placer of somewhat different type from those used in the tunnel. This placer then "shot" the material through an 8-in. pipe, approximately 200 ft. long, into a fourth hopper at the top of the construction adit of the surge shaft on the mountain side. The concrete then flowed by gravity from this hopper through a second 8-in. pipe and into the surge shaft forms, its final place of deposit.

The somewhat complicated method described above was adopted in order to utilize a part of the same set-up that had been used previously in placing the power house protection walls.

STRENGTH TESTS

In Fig. 11 are plotted the 28 day strengths obtained from the concrete placed in the main tunnel section. The curves show that the average strength was approximately 4000 lb. per sq. in. The average mix was 1:2:3 by dry loose volumes, and the average cement content 1.5 bbls. (6 bags) per cu. yd. of concrete. The surge shaft and penstock concrete gave approximately the same result.

GROUTING

Several months after the completion of the concreting operations the entire tunnel was grouted in order to give it additional strength and water tightness. In the roof of the arch section of the main tunnel, where the cavities were comparatively large, a rich mortar was used for this purpose, while in the other sections a neat cement mixture was used. The grout, or mortar, was forced into place through a hose by means of a grout pump or mixer, capable of exerting pressures up to 100 lb. per sq. in. Holes drilled at regular intervals through the concrete lining in the roof of the tunnel provided the necessary connections for the hose for forcing the grout into place (Fig. 10).

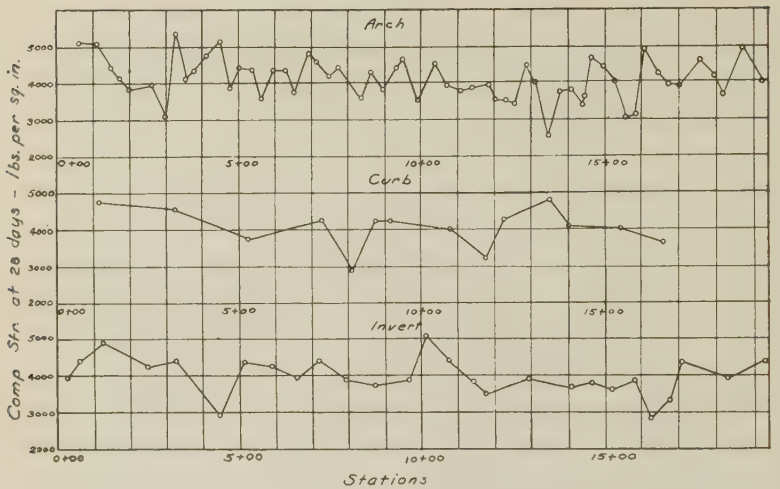

FIG. 11—TUNNEL CONCRETE STRENGTHS AT 28 DAYS

CONCLUSION

The success of a concreting operation using the methods described is dependent in a large degree on the proper co-ordination and co-operation of the different units involved. Without this co-operation costly delays may occur to upset the entire cycle of operations, thus running the costs up appreciably.

Acknowledgment is therefore made to those in responsible charge of this work for their co-operation with the writer in obtaining the results they did. The writer also wishes to thank in particular R. F. Taylor and E. B. Rayburn who, in their capacity as inspectors, worked tirelessly to obtain a high quality of concrete and its proper placement in the finished job.

Calderwood Development was designed under the direction of James W. Rickey, Chief Hydraulic Engineer of Aluminum Company of America, by James P. Growdon, Principal Assistant Hydraulic Engineer. I. G. Calderwood was the General Superintendent of Construction, under whose direction the tunnel was built.

Readers are referred to the JOURNAL *for December, 1931, (Vol. 28) for further discussion which may develop. Such discussion should reach the Secretary by Nov. 1, 1931.*

Field Practices in Using Concrete Aggregates In Multiple Sizes*

BY T. C. THEE†

The division of Management of the United States Bureau of Public Roads is entering its eighth year of study of highway production problems and of the methods of eliminating waste in the construction of highways.

Studies of construction methods and equipment are conducted in all parts of the United States and include nearly all types of highway construction projects, including portland cement concrete, asphaltic concrete, sheet and sand asphalt, bituminous macadam and brick pavement. The grading work includes power shovels, elevating graders, wheeler and fresno outfits. Miscellaneous studies include drilling and blasting operations, aggregate crushing plants, local pit plants, etc.

Field investigational work is in constant operation to study possible changes that can be recommended further to reduce cost without sacrifice of quality. We hold quality of work as paramount. In these attempts to reduce costs and at the same time maintain quality we feel that we have made steady progress. The studies are cooperative, in which the Bureau, State and County highway officials are all concerned.

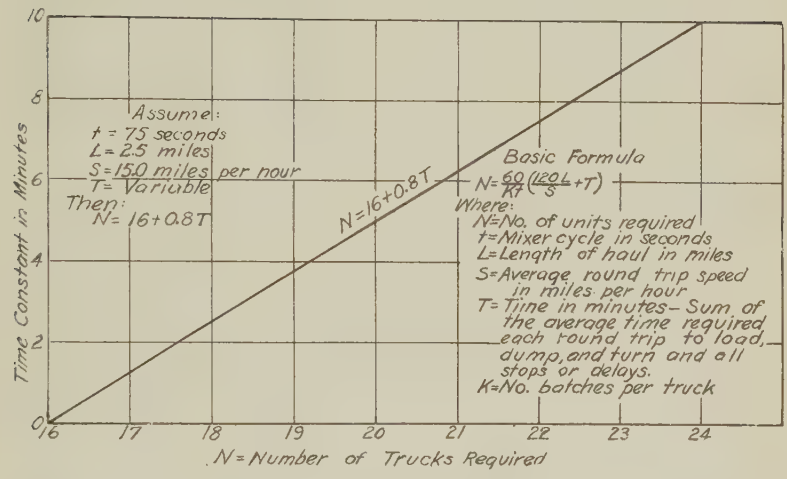
Coarse aggregate in separated sizes is now being used by the states to some extent where the maximum size is 1½-in. or more, or where a foreign aggregate is brought in to be incorporated in the mix to meet grading specifications.

Three states, California, Washington and New Jersey, require coarse aggregate to be batched in two sizes under all conditions. North Carolina, Louisiana, Georgia, Arkansas, Maine and Vermont require two-way batching under certain conditions.

*Presented at the 27th Annual Convention, Milwaukee, Feb. 24-26, 1931, with discussions by Messrs. Hambrecht and Langley, which follow in these pages.

†Assistant Highway Engineer, Division of Management, Bureau of Public Roads.

A few other states have used, or are using, two-way batching on special projects. Wisconsin tried three sizes of coarse aggregate on special projects last year, and on one project four sizes. No state requires a three-way split in batching. One state tried three sizes but has returned to the use of two sizes of coarse aggregate.



This separation of sizes is to eliminate as much as possible the segregation that takes place in car delivery and in stock piling the material, so as to maintain uniform gradation of the coarse aggregates and to reduce the batch-to-batch variation.

In using separated sizes of coarse aggregate the states specify the grading for each size. The point where the separation should be made is stated in the range of size. For example, No. 1 aggregate would be from 2½ in. to 1 in. and No. 2 aggregate from 1 in. to ¼-in. The material is delivered by rail in these two sizes. Two separate stock piles are maintained for these and one stock pile for the sand. Modern three compartment bins should be used and the three aggregates weighed separately. Moisture adjustments are made on the separate sizes and on the sand. The percentage of each size of coarse aggregate is adjusted to meet specifications and to obtain the least void content in relation to the best gradation and economy of aggregate production.

From the standpoint of batcher operation there is but little objection to two-size batching of the coarse aggregate where three-compartment bins are available. The real difficulties come in finding room for three instead of two stock piles, and in getting cars spotted correctly, as well as having each shipment carry the proper amounts of each size and the proper gradation.

Delays sometimes occur also at the beginning of a job or even in the progress of a job, due to variations at the producer's plant in the gradation of each size of the specified aggregates. As a consequence, the mix is often changed and this again may result in delays to the contractor because of the difficulty in ordering accurately the proper amount of each size.

These are all matters of real importance which cannot be forecast with precision. They do add to the difficulties with which the contractor has to contend and increase the opportunities for delay.

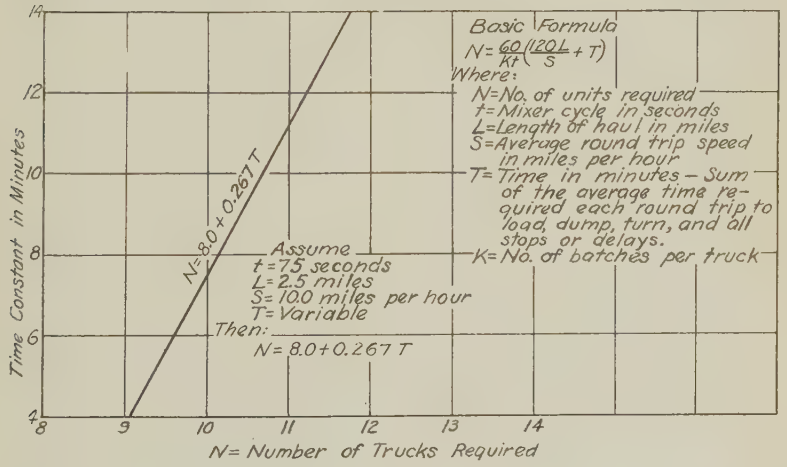


FIG. 1—EFFECT OF TIME CONSTANT ON THE NUMBER OF ONE BATCH TRUCKS REQUIRED ON CONCRETE PAVING

FIG. 2—EFFECT OF TIME CONSTANT ON THE NUMBER OF THREE BATCH TRUCKS REQUIRED ON CONCRETE PAVING

With the modern three-compartment batcher the time required for handling the three-way batch (two sizes of coarse aggregate and one of sand) is very little greater than for the two-way (one size of coarse aggregate and one of sand). Either type can be loaded while the truck is driving in, and the batch dropped in from 10 to 15 seconds, which is the length of the necessary stop for a one-batch truck. Even a three-batch truck is readily loaded with the three batches of sand and two sizes of stone or gravel in 75 seconds.

Where two bins are used the truck "time constant" is of course increased by the time required to get in position at the second bin and receive the batch or batches of the material handled by the second bin. A second bin reduces the crane operating time, through time lost in moving the crane from stock pile to stock pile and bin to bin. If the yard layout is poor, the time lost in moving the crane and the truck "time constant" may be considerable. This loss may be as much as three minutes for a three-batch truck, necessitating one or two extra trucks on the average job. This item alone is costly. Figs. 1 and 2 show the effect of time constants on the number of trucks required.

Stock piling practice varies so greatly and the requirements imposed by the states are so different that really comparable data are few. Under average conditions, when loading from cars to bins the crane cycle seems to vary between 30 and 45 seconds, depending on the skill of the operator, the angle of swing, and the general working conditions. When the car is nearly empty the rate usually is considerably slower. The fastest rate is usually obtained in working from a full car to stock pile, when if the swing is short the cycle may be as low as 25 seconds. The rate of operation does not seem to be appreciably affected by the size of the crane. That is, of two cranes in equally good condition the larger may be expected to operate on about the same cycle as the smaller. This seems to hold good at least for sizes from ¾ to 1½ cu. yd.

The most efficient contractors are finding it difficult to unload cars, stock pile, and fill the bins during the day and have to resort to several hours operation of the crane at night.

On the basis of a 60-second mixing time, a 30-cu. ft. batch, averaging 45 batches per hour using five sacks of cement per

cu. yd. of concrete, and a workability factor b/b_o of 0.76, 63,900 pounds of sand and 114,300 pounds of gravel will supply the 27-E paver per hour or a total of about 60 cu. yd. of material per hour.

With a crane averaging a cubic yard of material per bucket with a 35-second cycle, approximately 90 cu. yd. of material would be handled by the crane per hour, with allowance for necessary delays. This means that under favorable conditions the crane can produce about 50 per cent more than the requirements of the mixer if the material is loaded directly from cars to bin. If the material has to be stock piled first, then the crane would have to operate unloading cars partly at night. If material is delivered by trucks either from a nearby commercial plant or a local plant, the crane can easily maintain the necessary supply within the regular hours.

On the basis of a 50-second mixing time with a 33-cu. ft. batch, the crane will have available approximately 18 per cent leeway to load from cars to bins direct. However, if the specifications are such that two bins must be used, using three sizes of coarse aggregate, two cranes will have to be employed.

Where three sizes of coarse aggregate are delivered to a job by rail and three-batch trucks are used, the requirement of three sizes of coarse aggregate will cost the state indirectly through the

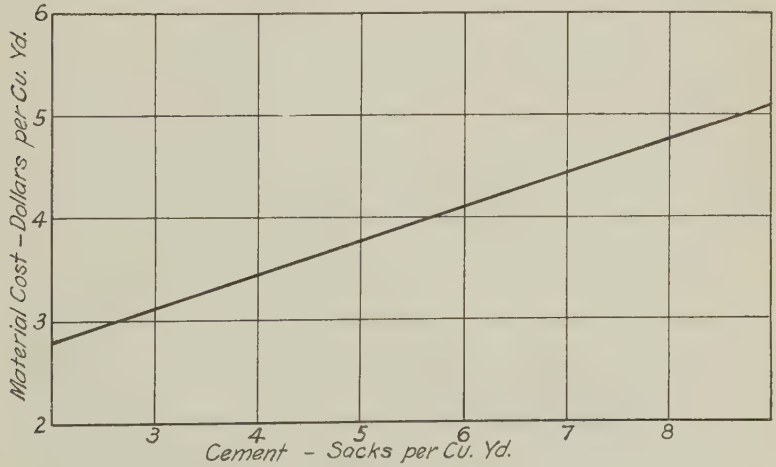

FIG. 3—EFFECT OF CEMENT CONTENT ON COST OF CONCRETE

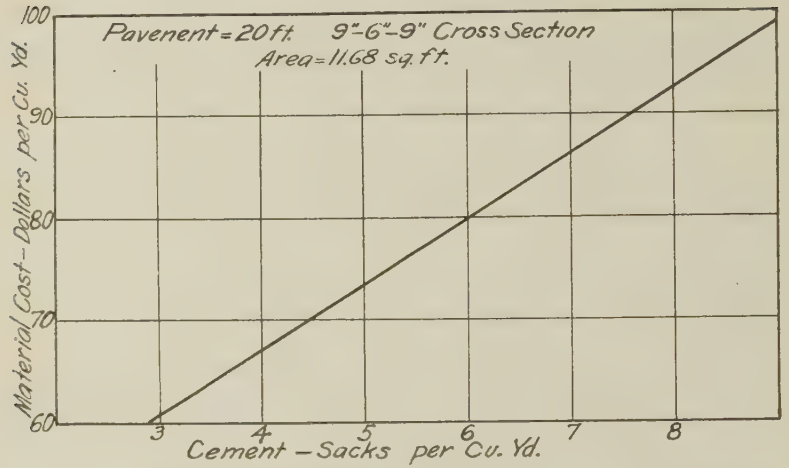

FIG. 4—EFFECT OF CEMENT CONTENT ON COST OF CONCRETE

contractor about $105 per day, or an average of $630 per mile, or 5.4 cents per sq. yd. of pavement. This is a cost equivalent of adding 0.78 sacks of cement to a 33-cu. ft. batch. Fig. 3 and 4 show the effect of cement content on the cost of pavement per cu. yd. and per sq. yd. respectively.

With a local or commercial plant delivering by trucks, the three sizes of coarse aggregate will cost approximately 1½ to 2 cents per square yard more than two sizes. No accurate average costs are available showing how much more three sizes of coarse aggregate cost to produce over one or two sizes.

Two projects were selected in Sheboygan county, Wisconsin, for special study of the use of multiple sizes of coarse aggregate and to investigate the effect of mixing time and batch size on the uniformity of ingredients of the concrete produced by 27-E pavers, and on the uniformity of resulting strength of concrete both for compression and transverse strength. The associated unit costs were also collected and studied. Before these two jobs were advertised to bidders careful laboratory experiments were conducted by the Wisconsin Highway Department to determine the desired grading and mix to use with the different sources of supply of aggregate materials. No discrimination was made between the different brands of cement available, although some difference existed.

On these two Wisconsin projects—S. A. P. 2916 and S. A. P. 2926—three sizes of coarse aggregate were specified with definite grading requirements. Five sacks of cement per cu. yd. of concrete as the minimum and six gal. of water per sack of cement as the maximum, were recommended so as to produce at least 650 lbs. per sq. in. transverse strength at 28 days.

The mixes on both jobs were designed for the minimum allowable cement content and maximum allowable water content. The workability of the concrete was maintained through the adjustment of the gravel and sand content employing the workability factor b/b_o as developed by Richart and Talbot. The method is shown graphically and the process of establishing the mix can be interpreted from the chart, Fig. 5. A workability factor b/b_o ratio of 0.76 seemed to work best on both jobs. The dashed line on the chart shows the mix developed on the basis of a b/b_o ratio value of 0.76.

The three sizes of aggregates were also recombined experimentally using different percentages of each size, in order to obtain as low a void content as possible without sacrifice of gradation in obtaining workable concrete.

The proportions of the various sizes as required by the specifications are as follows for S. A. P. 2926 (Sheboygan county, Wisc.).

No. 1	2½ in. to 1½ in.	30-35 per cent
No. 2	1½ in. to ¾ in.	45-50 per cent
No. 3	¾ in. to ¼ in.	15-25 per cent

No. 1 Coarse Aggregate, 2½ in.-1½ in.

	Per Cent
Retained on 3 in. circular opening	0
Retained on 2½ in. circular opening	0- 10
Retained on 1½ in. circular opening	90-100
Retained on 1¼ in. circular opening	100

No. 2 Coarse Aggregate, 1½ in.-¾ in.

	Per Cent
Retained on 1¾ in. circular opening	0
Retained on 1½ in. circular opening	0- 10
Retained on ¾ in. circular opening	90-100
Retained on ½ in. circular opening	100

No. 3 Coarse Aggregate, ¾ in.-¼ in.

	Per Cent
Retained on 1 in. circular opening	0
Retained on ¾ in. circular opening	0- 5
Retained on ¼ in. circular opening	95-100

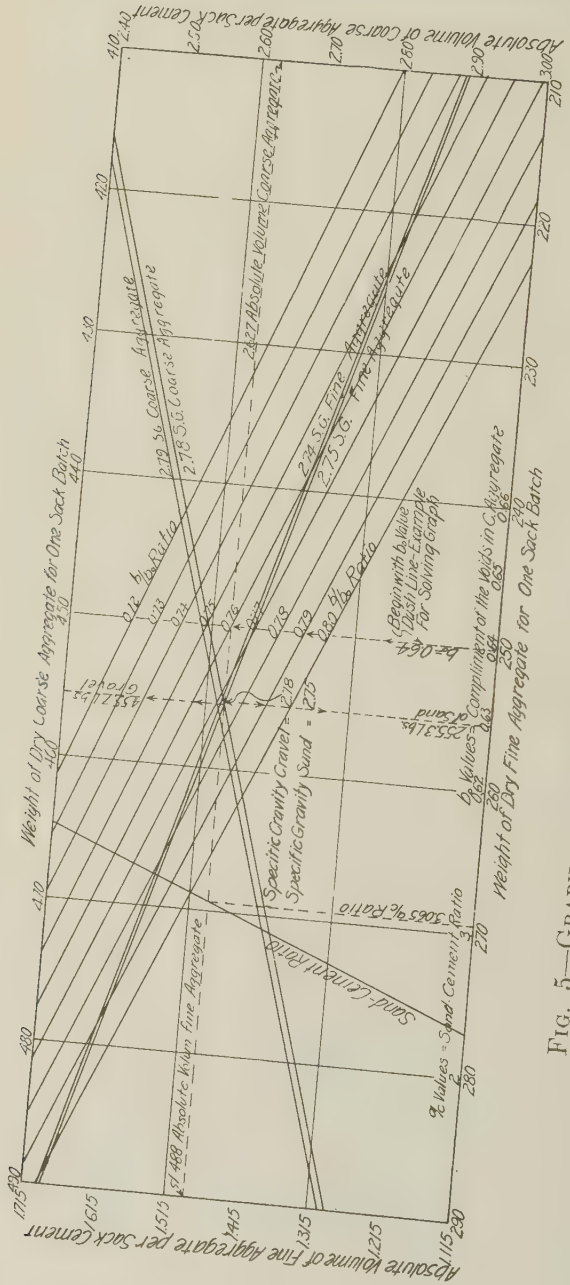

FIG. 5—GRAPH FOR AGGREGATE ADJUSTMENT IN MAINTAINING WORKABILITY WITH FIVE SACKS CEMENT PER CUBIC YARD OF CONCRETE AND 6 GALLONS OF WATER PER SACK OF CEMENT

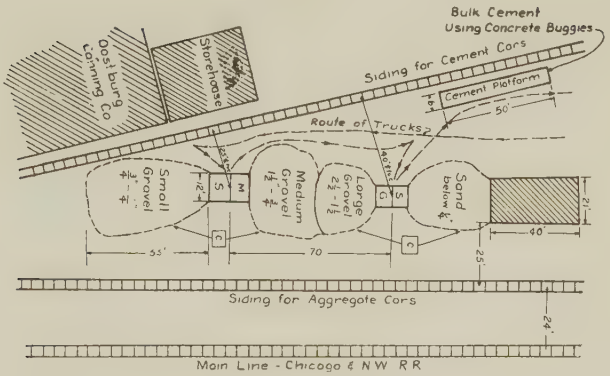

FIG. 6—PLANT LAYOUT, WISCONSIN S. A. P. 2916, SHEBOYGAN COUNTY—THREE SIZES OF COARSE AGGREGATE

Figs. 6 and 7 show the plant layout and set-up on Wisconsin S. A. P. 2916. It is obvious that a very crowded condition existed. Using three sizes of coarse aggregate made it very cumbersome. The plant was such that trucks lost on an average of two minutes over a typical set-up, resulting in the use of one and sometimes two trucks more than would normally be used; an extra crane was required; the material was delivered by rail.

FIG. 7—PLANT SET-UP, S. A. P. 2916, SHEBOYGAN COUNTY, WISCONSIN, USING THREE SIZES OF COARSE AGGREGATE AND ONE OF SAND; MATERIALS DELIVERED BY RAIL

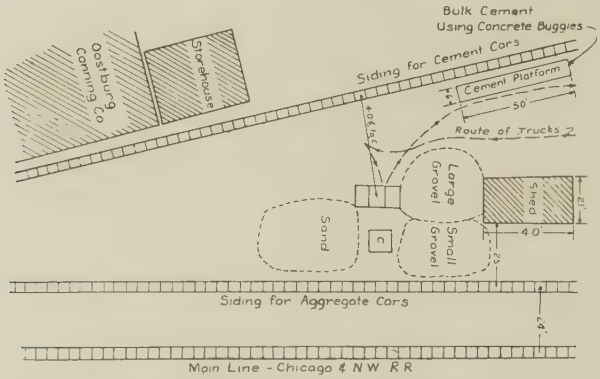

FIG. 8—SUGGESTED PLANT LAYOUT, WISCONSIN S. A. P. 2916, SHEBOYGAN COUNTY—TWO SIZES OF COARSE AGGREGATE

Fig. 8 shows the same plant site but with equipment and stock piles planned for handling two sizes of coarse aggregate. This set-up would not result in any greater cost than for only one size of coarse aggregate.

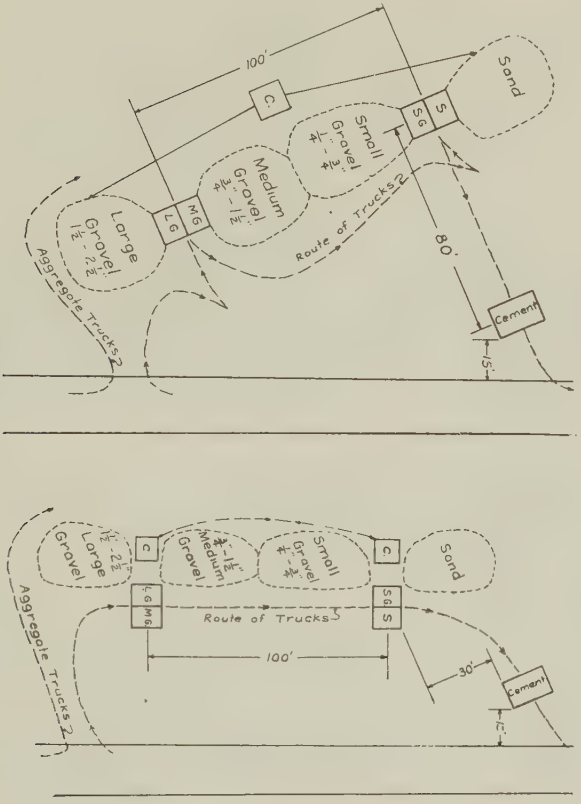
Fig. 9 shows the plant on one set-up on Wisconsin S. A. P. 2926, showing the number of turns that were required by the trucks on this job.

Fig. 10 shows the same set-up with a recommended change that could be used on similar jobs. Turning time for the trucks will be eliminated.

If but two sizes of coarse aggregate were used a three-compartment bin could have been used with one stop for the trucks. This would have been a most economical set-up and still have utilized the advantage of multiple size aggregates.

On S. A. P. 2926 the material was delivered by truck from a local pit and only one crane was necessary to supply the mixer when a 33-cu. ft. batch and a 50-sec. mixing time were used, with an average of fifty-five 33-cu. ft. batches an hour. This means that the crane handled 238,931 lbs. of sand and gravel per hour average, or about 80 cu. yds. of material per hour.

Fig. 15 shows a set-up observed this summer handled by one crane and straight-line loading method. Bulk cement was placed in the batch between the stone and sand which eliminated cover-



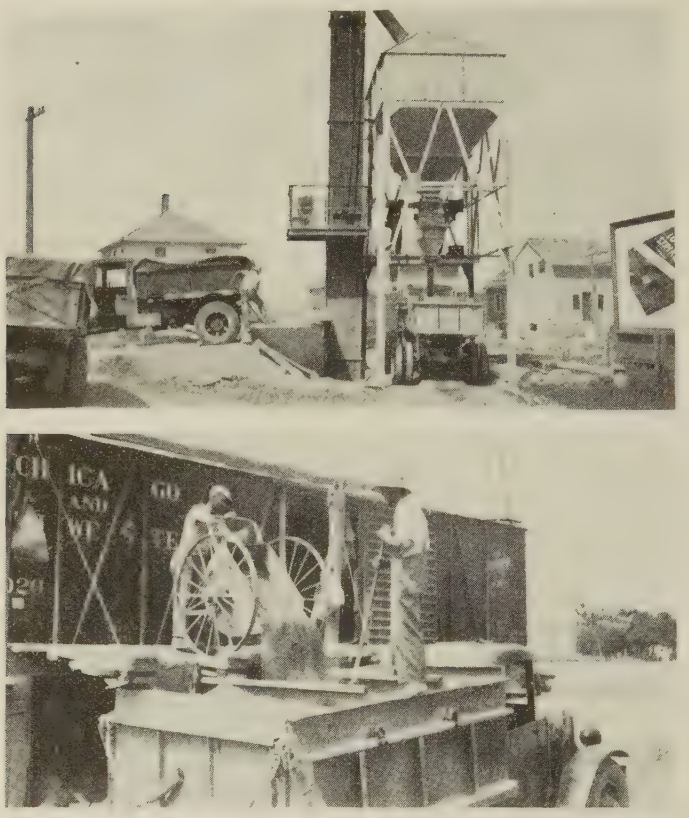


FIG. 9—PLANT LAYOUT, WISCONSIN S. A. P. 2926, SHEBOYGAN COUNTY—THREE SIZES OF COARSE AGGREGATE

FIG. 10—SUGGESTED PLANT LAYOUT, WISCONSIN S. A. P. 2926, SHEBOYGAN COUNTY—THREE SIZES OF COARSE AGGREGATE

ing the cement. This method proved very satisfactory. It eliminated having cement dumped into the skip first and choking the throat of the skip so as to retard material entering the drum. This method also eliminates the cement hitting the blades and bucket of a mixer drum causing them to become badly coated and reduce their efficiency. Some engineers prefer to have the order of loading changed to second size aggregate, sand, cement and then coarse aggregate.

FIGS. 11 AND 12—METHODS OF HANDLING CEMENT IN BULK ON S. A. P. 2916 AND S. A. P. 2926, SHEBOYGAN COUNTY, WISCONSIN

Incidentally, this contractor was using sack cement and obtained permission to try bulk cement, at a saving of eleven cents a barrel. Use of cement in bulk assures the proper weight of cement, enables a contractor to maintain a constant maximum batch and eliminates the cost of handling empty sacks. The cement retained in the sacks will average 0.4 lb. per sack. A state buying cement can make a large saving in the last mentioned item alone. As its advantages become more generally appreciated, it is believed the use of bulk cement will be extended. Up to the present time the most popular way of handling cement

FIG. 13—TYPICAL PLANT SET-UP, S. A. P. 2926, SHEBOYGAN COUNTY, WISCONSIN. MATERIAL HAULED BY TRUCK FROM LOCAL PIT—COARSE AGGREGATE IN THREE SIZES

FIG. 16—COST CHART FOR CONCRETE PAVING PROJECT 1

Cement hauled by truck directly to bulk cement plant. Aggregates from local producing plant—cost includes delivery to batching plant. Depreciation figured on 11.27 miles of pavement—life of paver taken as 55 miles. Concrete design: 5 sacks of cement per cu. yd. of concrete, 6 gallons water per sack of cement, and b/b$_o$ of .76. Mix by weight—1:2.67:4.67. Total cost per sq. yd. $1.362. Length of project 11.273 miles. Average length of haul 1.96 miles.

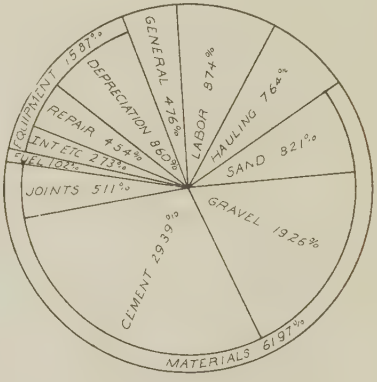

FIG. 17—COST CHART FOR CONCRETE PAVING PROJECT 2

Cement delivered in bulk by rail and handled in carts. Aggregates from commercial plant, delivered by rail—cost includes freight. Depreciation figured on 10.00 miles of pavement—life of paver taken as 50 miles. Concrete design: 5 sacks of cement per cu. yd. of concrete, 6 gallons water per sack of cement, and b/b$_o$ of .76. Mix by weight—1:2.71:4.68. Total cost per sq. yd. $1.472. Length of project 9.88 miles. Average length of haul 1.97 miles.

and finally dump the cement into the trucks.

On Wisconsin S. A. P. 2916, (Figs. 6, 8 and 12), the bulk cement was delivered by rail and the concrete buggies employed to handle the cement. On Wisconsin S. A. P. 2926 the cement was delivered on the job in trucks and the cement loaded mechanically. Both methods proved very satisfactory and the trucks could be loaded rapidly with no apparent loss of cement during loading or in transit. Sand was dumped on the coarse aggregate so that it could be pocketed and the bulk cement covered with the loose sand. Both jobs employed straight-line loading of the trucks with the bulk cement. This eliminated unnecessary turning or backing of the trucks.

Delaying a three-batch truck one minute represents a loss

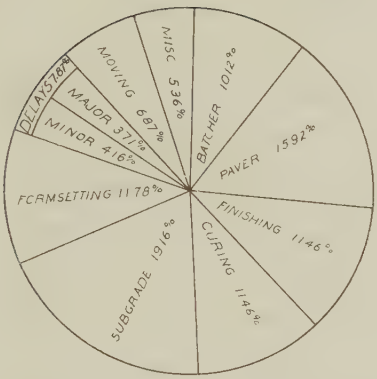

FIG. 18—LABOR COST CHART FOR CONCRETE PAVING PROJECT 1

Major delays: Unavoidable delays over 15 minutes in duration. Minor delays: Unavoidable delays under 15 minutes in duration. Cement handled by bulk cement plant and delivered directly by trucks. Moving includes that occurring during job. Concrete design: 5 sacks cement per cu. yd. of concrete, 6 gallons water per sack of cement, and b/b$_o$ of .76. Mix by weight—1:2.67:4.67. Total cost per sq. yd. $0.1260. Length of project 11.273 miles. Average length of haul 1.96 miles. Hauling by sub-contract—labor not included on chart.

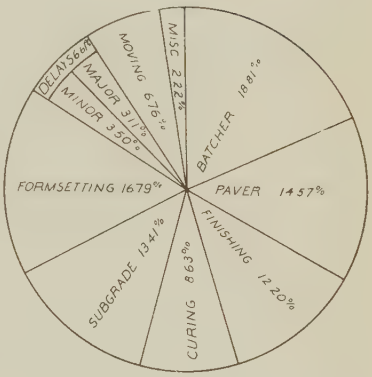

FIG. 19—LABOR COST CHART FOR CONCRETE PAVING PROJECT 2

Major delays: Unavoidable delays over 15 minutes in duration. Minor delays: Unavoidable delays under 15 minutes in duration. Cement handled in carts and delivered in bulk by rail. Moving includes that occurring during job. Concrete design: 5 sacks cement per cu. yd. of concrete, 6 gallons water per sack of cement, and b/b$_o$ of .76. Mix by weight—1:2.71:4.68. Total cost per sq. yd. $0.1287. Length of project 9.88 miles. Average length of haul 1.97 miles. Hauling by sub-contract—labor not included on chart.

of about five cents. This item may seem small but it accumulates rapidly into a larger sum. Delaying the mixer one minute often represents a loss of about one dollar. On a paving job where operations should synchronize and coordinate, seconds lost are dollars wasted. An efficient batching plant removes many chances for delay.

Tables 1 and 2 show summaries from the time studies made during June to October on the Sheboygan county, Wisconsin, jobs. These data were obtained by careful stop-watch studies made every day of all operations to determine the mixer delays in seconds of less than fifteen minutes in duration, which were classified as minor delays, and delays of greater than fifteen minutes, which were grouped as major delays. In both minor and

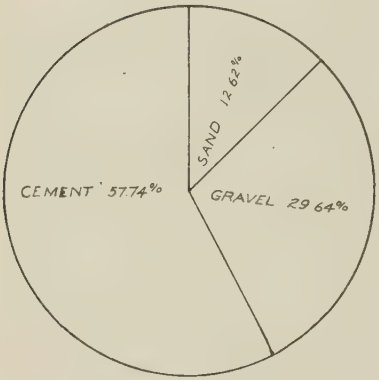

FIG. 20—COST CHART FOR CONCRETE MATERIALS PROJECT 1

Aggregates from local producing plant—cost includes delivery to batching plant. Bulk cement used. Concrete design: 5 sacks cement per cu. yd. of concrete, 6 gallons water per sack of cement, and b/b$_o$ of .76. Mix by weight—1:2.67:4.67. Total cost per sq. yd. $0.749. Length of project 11.273 miles. Average length of haul 1.96 miles.

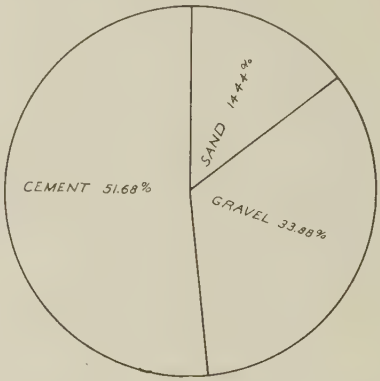

FIG. 21—COST CHART FOR CONCRETE MATERIALS PROJECT 2

Aggregates from commercial plant, delivered by rail—cost includes freight. Bulk cement used. Concrete design: 5 sacks cement per cu. yd. of concrete, 6 gallons water per sack of cement, and b/b$_o$ of .76. Mix by weight—1:2.71:4.68. Total cost per sq. yd. $0.837. Length of project 9.88 miles. Average length of haul 1.97 miles.

major delays, those believed to be unavoidable were classified as "A" and those believed to be avoidable as "B."

In noting the losses that occurred on the job, delays due to separated sizes are negligible, except on the job where the plant space was limited because of the four stock piles and the crowded conditions that existed. The job started with one crane but as production was improved. another crane had to be put on the job. Probable causes of delays were forecast on the job and through the contractor's cooperation in using suggestions to remedy them, delays of any consequence due to handling the separated aggregates did not occur.

Figs. 16-21 show the data collected on the Sheboygan county jobs. These charts illustrate the costs involved in constructing the concrete pavement, where both jobs had practically the same truck haul with the overall efficiency of one contractor 83.1 per cent, and the other 88.0 per cent. One job used local aggregate

FIG. 24—METAL SAMPLE BUCKETS AND BEAM MOLDS IN POSITION TO RECEIVE CONCRETE AS DUMPED FROM MIXER SPREADER BUCKET

FIG. 25—REMOVING SAMPLE BUCKETS AND BEAMS FROM THE SUBGRADE TO THE BERM OF THE ROAD WHERE ANALYSIS IS MADE ON THE FIVE PARTS OF THE BATCH FOR THE EXACT AMOUNT OF GRAVEL, SAND, CEMENT AND WATER

and the other commercial aggregate; five sacks of cement per cu. yd. on each job.

Previous to 1930 approximately six sacks of cement were used per cubic yard of concrete on most State and Federal paving jobs. By selective grading and reducing the void content of the coarse aggregate on these two jobs, the cement reduction to five sacks per cu. yd. was made without loss of strength. A saving of approximately 6.5 cents per sq. yd. was made. Even with this reduction of cement content, the cement still forms about 30 per cent of the total cost of the pavement, and on the

FIG. 26—WASHING THE CEMENT OUT OF THE SAMPLES OF CONCRETE THROUGH A NEST OF NO. 4, 48 AND 100-MESH SIEVES

basis of the cost of the materials alone—that is, the gravel, sand and cement—the percentage is over 50 per cent. (Investigations are in progress to study the effect of cement content on the durability of concrete.)

Further reductions in hauling, labor and depreciation will be made next year in Wisconsin by the use of a 33-ft. batch and a 50-sec. mixing time after all solid material are in the drum.

On these two Sheboygan county jobs and on a Federal-aid project in Arkansas, 242 batches were sampled as they were dumped on the subgrade and tests made to determine the exact amount of coarse aggregate, sand, cement and water in samples taken from the four corners and center of the batch. From these same batches, beams and cylinders were also made—a total of 1,276 cylinders and 726 beams. Cylinders were broken at 28 days and the beams once at 7 days and twice at 28 days. The curing was the same on all jobs. The gravel obtained from the concrete sampled in the field was sieved.

These data were all obtained in connection with our study of batch size and mixing time. Table 3 gives the grand total of all data collected on each job.

The Sheboygan jobs show a slightly higher cement content than five sacks per cu. yd., because less water was used than anticipated. The water content was supposed to have been six gal. per sack of cement.

FIG. 27 (LEFT)—WEIGHING EACH BATCH PART IN AIR AND THEN IN WATER, USING THE APPARATUS SHOWN. WEIGHING WAS ACCURATE TO $\frac{1}{16}$ OUNCE

FIG. 28 (RIGHT)

One cylinder was obtained from the four corners of the batch and two from the center. Three 6 x 8 x 42-in. beams were taken from each batch. Cylinders made according to the A. S. T. M. methods. Beams were only rodded at the edges without disturbing the center mass of concrete.

On the Arkansas job the cement was supposed to have been 5.40 sacks per cu. yd. of concrete and 5.25 gal. of water per sack of cement. Because of the high temperature and high evaporation, more water was used.

The coarse aggregate used in Arkansas was a crushed trap rock and in Sheboygan, Wisconsin, a limestone gravel. The maximum size of aggregate on both jobs approximated 2½ in.

The variation on all the jobs approximate each other within one per cent and are fairly comparable in regard to actual cement and water content. Please note that the variations from batch to batch were less than the variations within the batch.

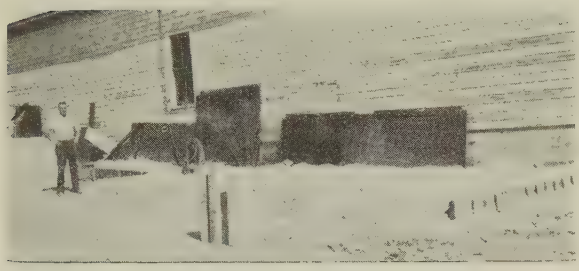

FIG. 29

Beam specimens were cured in damp sand for 28 days and tested in the field. Cylinders were cured at the same location as beams and removed in time to send to the Madison, Wisconsin, State Forestry Laboratories to be tested at 28 days.

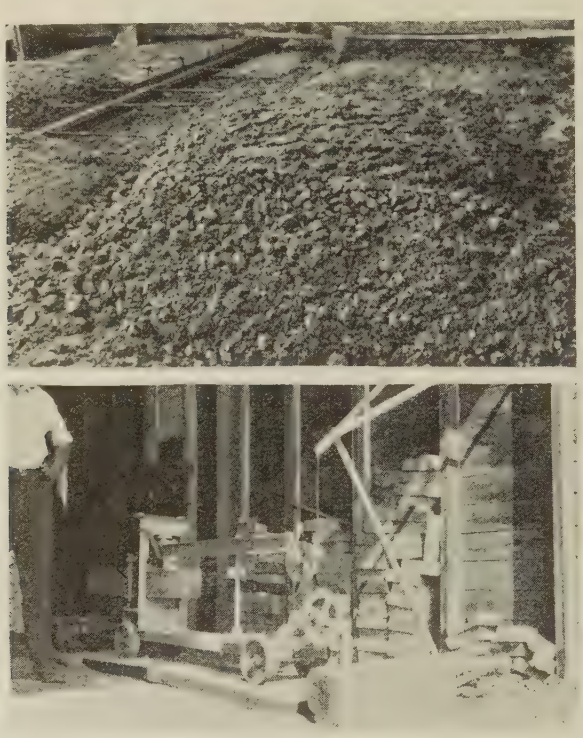

FIG. 30

The last cubic foot of concrete discharged from any make of mixer has a predominance of coarse aggregate. Therefore approximately a cubic foot of concrete should be retained in the mixer drum. Also the design of mixer spreader bucket causes segregation. The results of these two cause a batch to appear such as shown in the above photograph.

FIG. 31—THE BEAM TESTING MACHINE AND THE LOAD OF APPLICATION WAS CONTROLLED TO BE THE SAME ON ALL SPECIMENS AND TESTED BY THE SAME OPERATOR

Even by visual inspection one could see on these jobs that variations from batch to batch were reduced by using separated sizes for the coarse aggregates. This was valuable in reducing delays at the mixer, where ordinarily a concrete produced with a very low water content and low cement factor gives occasionally an extremely dry batch which almost invariably delays the finishing operations.

Variations within a batch will apparently be hard to eliminate

no matter what the size of the batch (our tests cover batches varying from 27 to 35 cu. ft. in a 27-E paver), or whether the concrete is mixed more than 50 seconds after all the solid materials are in the drum. The variations within a batch become larger as the range from small size aggregate to large size aggregate becomes larger.

In general terms a slab is no stronger than its weakest batch, and each batch is no stronger than its weakest part. Therefore, we must work toward the most advantageous equalization of both the variations between batches and the variations within the batch. It follows we should not attempt to have the variation from batch to batch reduced by too costly refinements below the variation within a batch. This, I believe, is the answer to the question, "How many separated sizes of coarse aggregate should be used?"

To reduce variations from batch to batch beyond a certain point costs money. In some, probably many cases, the use of separated sizes of coarse aggregate can be made to yield a net profit. The extent to which this process can be pushed, however, seems to have a definite limit, in that the cost is likely to increase progressively as the variations are reduced. To press the reduction in the variations from batch to batch too near the same value as the variations within the batch would therefore bring us within the field of diminishing returns. And to bring the variations between batches below the variations existing within the batch would seem to be of little use, even though this could, by some happy chance, be accomplished at no extra cost.

If oversanded mixes are still retained after the introduction of the use of aggregate of multiple sizes, the added expense is a loss. It is obvious that by using separated sizes intelligently a lower mortar ratio can generally be used, and as a consequence the cement factor can be reduced. The extent to which this can be done for any given extra cost will form a measure of what saving can be expected from using separated sizes of coarse aggregate in concrete road construction.

DISCUSSION

BY A. L. HAMBRECHT*

The Department of Commerce reports show one hundred million barrels of cement manufactured in 1920 which represents an increase of approximately 26 per cent over the amount manufactured in 1910 and a further increase of approximately 70 per cent from 1920 to 1930. A large part of the increase shown for the 1920-1930 decade is accounted for by the increased highway construction programs of that period.

To meet the demands of the added construction there followed a development and improvement of various types of paving equipment which is probably unparalleled in any other line of industry. Compare the modern concrete paving outfit of comparatively few men and nearly perfect coordination between the various units with the more or less disjointed, inefficient paving outfit commonly used prior to 1920—a large number of men who spent a considerable part of their time side-stepping to avoid colliding with each other—wooden forms in various stages of disintegration—stock piles of aggregates on the subgrade, more likely than not covered with a liberal layer of dust—a maze of plank runways—a collection of decrepit wheelbarrows—a wheezy old alley steam paver—and last but not least the man-killing, hand operated strikeoff boards. As we contemplate this we cannot help but wonder why the old order held forth as long as it did.

The sudden and unprecedented increase in the use of portland cement concrete for paving caught highway engineers more or less unprepared with the result that, except in a few isolated cases, the art of concrete manufacturing from the standpoint of the concrete itself did not receive a great deal of attention. Arbitrary proportions were specified—the aggregates were proportioned by volume without correction for bulking—the amount of mixing water added to the batch was left entirely to the judgment of the mixer operator with the result that the batch to batch consistency varied greatly.

The importance of controlling and maintaining uniform amounts of aggregates in the batches and maintaining a uniform con-

*Construction Engineer, Wisconsin State Highway Commission.

sistency was recognized and resulted in the almost universal adoption of weight proportioning and the installation of accurate water measuring devices on paving mixers.

The several theories of proportioning and designing concrete mixtures whether it be by arbitrary assignment, fineness modulus, maximum density, water cement ratio or voids recognize the importance of maintaining uniform proportions of the materials if uniform results are to be obtained. This necessitates accurate measurement of all materials. The character of sand is such that segregation in handling is negligible and the volume of the given sand is approximately uniform when dry. Sand can easily be weighed to a high degree of accuracy and moisture corrections easily and accurately made. The coarse aggregate, however, presents a more difficult problem. By weighing a definite absolute volume can be maintained. The apparent volume, however, will vary as the gradation varies. When we consider that we are dealing with a material with a range in gradation from 2½ in. to ¼ in. or 1½ in. to ¼ in., and the frequent handling required between the producing plant and the placing in the forms it becomes apparent that wide variations can and do exist from the gradations originally specified. Even with the utmost care in stock piling we find an accumulation of finer particles in the center and an excess of coarser particles on the outside of the pile.

The tendency of coarse aggregate to segregate and the resulting variation in apparent volume, voids and surface areas, which in turn affect uniformity of water content, mortar content, workability and yield is a real obstacle to concrete control. Variations of 15 per cent in the voids of equally proportioned coarse aggregates due to segregation and poor gradation frequently occur and such variations can easily cause a 10 per cent batch to batch variation in cement content per unit volume of concrete.

The separation of coarse aggregate into several sizes, thereby maintaining the voids at a uniform minimum and the use of a uniform minimum amount of mortar consistent with workability will tend to insure a reasonably uniform product for any given combination of materials.

During the 1930 construction season the use of coarse aggregates in separated sizes was required by the Wisconsin Highway Commission on a number of paving and bridge projects. The

materials used consisted of those most commonly used in concrete work in this state, namely, calcareous or dolomitic gravel, igneous or granitic gravel and crushed limestone. The aggregate for one project was produced from a local pit and the other projects were supplied by commercial plants.

The coarse aggregate for the paving projects was required to be furnished within the following gradations: limestone and calcareous type gravel in three sizes, ¼ in. to ¾ in., ¾ in. to 1½ in. and 1½ in. to 2½ in. Igneous type gravel in two sizes, ¼ in. to ¾ in. and ¾ in. to 1½ in. For bridge work the maximum size allowed is 1½ in.

The production of coarse aggregate in separated sizes whether by a commercial plant or by the contractor from a local pit will in most cases require plant changes consisting principally in providing increased screen capacity to permit a close separation of sizes. Commercial producers will readily agree to accept this method as they have for some time been attempting to effect a standardization of commercial sizes.

On our 1930 work, which can be considered of an experimental nature, no difficulty was experienced in securing the required sizes from commercial plants or in the local pit production.

In handling rail-shipped aggregates from cars to stock piles or proportioning bins, side track and yard space available will control the size of stock piles and general arrangement of plant and equipment. Two double compartment bins will be required when using three sizes of coarse aggregate and two cranes will be necessary to avoid delays except under the most favorable arrangements. The pictures shown by Mr. Thee give some idea of the restricted space available for stock piles, proportioning bins and cement handling platform on the Johnson job. The arrangement while inconvenient did not appreciably affect production.

On the project where two sizes were used a single crane easily kept the three compartment bin fully charged.

With the locally produced material the aggregates were hauled by truck from the producing plant and stock piled on an area adjacent to the project. The arrangement of bins and stock piles enabled a single crane to handle the material without causing any delays.

The use of two bins introduces added costs for equipment and the extra batch operator and involves some lost time for the trucks. The additional batching time required will depend upon the distance between and the accessibility of the bins. With two sizes of coarse aggregate, using a three compartment bin there was no noticeable increase in the time required for batching.

With all of the materials entering each batch accurately controlled the resulting concrete as deposited on the subgrade has a decidedly uniform appearance. There were no batches with an excess of coarse aggregate or an excess of mortar, a common occurrence on projects using a single size of coarse aggregate. Other factors being equal, uniformity of concrete will to a great extent eliminate the unequal shrinkage or settlement responsible for many of the present pavement surface irregularities.

The views showing the placing and finishing of the concrete indicate an excess of mixing water. This did not generally prevail on our work and we try to maintain a consistency which will give a slump of about 1½ in. and further limit the mixing water to 6 gal. maximum per sack of cement.

A comparison of results obtained on two projects, one using separated sizes and the other a single size, indicates that close control of the proportioning of aggregates produces concrete of greater uniformity. As the following will indicate, the projects were built at the same time of the year and were within 30 miles of each other. The aggregates were supplied from the same commercial plant and the proportions were identical except for the separated sizes. The average strength of the specimens using separated sizes was 11 per cent greater than the average strength using the single size. On the job using recombined aggregates all breaks were within 10 per cent above or below the average and of the total of 53 breaks only two tested more than 5 per cent above and only 6 tested more than 5 per cent below the average.

The variation in strengths on the job using the single size of stone ranged from 25 per cent above to 25 per cent below the average and of the total of 41 breaks 16 tested more than 5 per cent above and 16 tested more than 5 per cent below the average.

These results are generally typical of the results obtained on other projects.

An analysis of the concrete as it is discharged from the spreader

bucket indicates that there is a variation in the relative proportions of coarse aggregate, fine aggregate, cement and water in different parts of the batch. In a typical series of tests the following variations existed. The cement content varied from 4.79 sacks to 5.42 sacks per cubic yard. The water varied from 4.96 gal. to 5.45 gal. per sack of cement. The sand cement ratio varied from 2.99 to 3.14. The gravel sand ratio varied from 2.10 to 1.53 and the ratio of the absolute volume of coarse aggregate in a cubic foot of concrete to the absolute volume of coarse aggregate in a cu. ft. of coarse aggregate or the b/b_o varied from .845 to .749.

It is therefore evident that unnecessary refinements in gradation which would tend to increase costs would be unwarranted unless the interior of the mixer drum and spreader bucket can be designed to overcome the variations noted above.

The results obtained by the use of separated sizes of coarse aggregate on the 1930 work have convinced us that it is a construction detail that should be recognized in designing concrete mixes, when a relatively high percentage of coarse aggregate is used. The type and character of materials available and the combinations possible with them can materially affect the final cost without sacrificing quality.

BY GEO. LANGLEY, JR.*

My position as County Highway Engineer placing me, as it does, in direct field contact with construction work, and in direct contact with the people to whom I am responsible (the tax-paying public) necessarily inclines me to consider the theories involved in the design of concrete mixtures, from the thoroughly materialistic rather than from the profoundly abstract viewpoint.

From 1927 to 1930 inclusive, Sheboygan county has constructed 80 miles of portland cement concrete highway pavement.

In 1927, 5 miles were constructed using the Wisconsin Highway Commission specification, 1:2:4 proportioning with all measurements by volume.

Twelve miles were constructed in 1928 again using the Wisconsin Highway Commission specification 1:2:4 proportioning, the coarse aggregate measured by volume, and the fine aggregate

*County Engineer, Sheboygan County.

measured by weight with corrections for moisture content and bulking factor.

Thirty miles were constructed in 1929 using a designed mix, both aggregates being measured by weight, without separating and recombining the coarse aggregates.

Thirty-three miles were constructed in 1930 using a designed mix, measurements by weight and the coarse aggregate separated into three sizes and recombined in the batch.

Of these 33 miles about 23 miles were constructed under the observation of, and subject to tests by the Division of Management, U. S. Bureau of Public Roads. Specifications on this 23 mile construction called for the use of four different sized batches, 27, 30, 33 and 35 cu. ft. as directed by the engineer in charge. Unit prices were received on each batch size, the average contract price of the 27 cu. ft. being 3¢ per square yard greater than the 30 cu. ft. batch, and the 30 cu. ft. being 2½¢ more than the 33 or 35 cu. ft. batch.

Test results on the concrete produced during these four years were as follows:

Year	Flexural Strength		Compressive Strength		
	7 Day Beams Average Mod. of Rup. lbs. per sq. in.	28 Day Beams Average Mod. of Rup. lbs. per sq. in.	Cylinders 28 Days lbs. per sq. in.	Cores-Age 6 Months lbs. per sq. in.	Cement Content per cu. yd.
1927	None	None	None	None	1.6 Bbls.
1928	None	None	None	3960	1.39 Bbls.
1929	521	665	None	4250	1.24 Bbls.
1930	590	861	3665	To Date 5680	1.25 Bbls.

The tests taken and records kept during 1930 by the Division of Management, U. S. Bureau of Public Roads were very complete. Sheboygan county has a definite program calling for the construction of 45 miles of the same type of highway. It follows, of course, that we, desiring to profit by the records of past experience, are making an exhaustive study of these records.

The outstanding facts gleaned from our test records of the past four years are:

1st: An increase of 40 per cent in compressive strength in 1930 as compared to 1928.
2nd: An increase of 30 per cent in flexural strength in 1930 as compared to 1929.
3rd: Constantly increasing control of proportioning of aggregates.
4th: Constant decrease in the quantity of cement per cubic yard of concrete.
5th: Constant increase in rate of production.

Certainly, the increased strength of the concrete, together with an increase in density, should indicate increased durability, at least insofar as the effects of changes in temperature are concerned.

The decrease in cement content made possible by careful proportioning of the aggregates and the increase in production due to increase in batch volume and decrease in mixing time are, of course, of enormous economic value.

It will be noted by reference to Fig. 3 and 4 of Mr. Thee's paper that by decreasing the cement content from six to five bags per cu. yd. there was a reduction of 6½¢ per sq. yd. in the cost of the pavement. As Sheboygan county built 33 miles of concrete pavement last year, the saving in cement cost was $26,100.00.

The saving in cost due to the increase in the volume of the batch amounted to 5½¢ per sq. yd. Consequently, the saving due to this item was $21,240.00, or a total saving on the 33 miles of $47,340.00. This total of $47,340.00 was 20 per cent of the total general property tax for highway purposes in Sheboygan County in 1930.

It is evident from the records, that close control of the aggregates makes possible a considerable saving in cost.

In our experimental use of three sizes of coarse aggregate, we confined ourselves to the use of such equipment for this separation as was available and made every effort to avoid changes in this equipment.

Coarse aggregate proportions to fit the existent production conditions were used.

Screen equipment at production plants was such as to make it impossible to obtain efficient separation. An over run of sizes sometimes as great as 50 per cent was noted.

It is evident that if crushers are adjusted to produce coarse

aggregate in the most advantageous proportions and sufficient screen area used to insure complete separation, much closer control of the proportioning of the aggregates may be obtained.

Records from other localities show that coarse aggregate with a maximum size of three and one-half inches is being used with no detrimental effect on the strength of the concrete. The use of a 3½-in. maximum size of coarse aggregate would reduce the cost of production of the aggregate. It would also make it possible to obtain a larger percentage of absolute volume in a cubic yard of coarse aggregate.

Bins are already planned by equipment manufacturers to make it possible to load the truck with one stop, thus eliminating much of the extra truck cost of last season.

Inasmuch as it has been our experience to note, and our records plainly indicate, that as we gained closer control of the proportioning in the materials, the quality of the concrete improved and the cost decreased. I find it hard to accept Mr. Thee's conclusion that two sizes of coarse aggregate are sufficient.

Mr. Thee's conclusion is based, of course, on cost records of last year, and I fear that the methods used in the separating and recombining of the coarse aggregate were too crude to reflect true cost.

It seems possible that the continued use of three sizes of coarse aggregate may bring about more efficient equipment and methods, so that the benefits derived will warrant the cost.

I believe that with control of proportioning as near perfect as possible, the cement content per cu. yd. of concrete need not be arbitrarily specified, but that it is dependent on the gradation of the materials used.

It seems evident that if in a cubic yard of concrete, the greatest amount of absolute volume of coarse aggregate practical, from the viewpoint of workability, is used, the amount of mortar required will be the minimum.

It seems just as evident, that if the absolute volume in the quantity of sand required for the mortar is the greatest obtainable, the cement content requirement of the mortar will be the minimum.

Such a combination of materials should not require too large an amount of water to bring about the necessary degree of work-

ability, and even if too much water is placed in the mixture, the excess quantity will be eliminated in placing and finishing the slab, so that a proper water cement ratio will be effective before hardening takes place. It is our belief that the water cement ratio of concrete in a highway slab pavement is in no way affected by the quantity of water, within reasonable limits, placed in the mixer, provided, of course, that there is sufficient water to hydrate the cement used; also, that the quantity of water, after the concrete is in place on the subgrade and has received its final working, and is ready to set, establishes the effective water cement ratio, and that this ratio is to a considerable extent dependent upon the gradation of the dry materials used in the concrete.

If materials of a proper gradation are obtainable, a computation of proportions is both possible and plausible, and this computation is a matter of field practice and does not necessarily need laboratory test.

To me the test records of our work of last season indicate that the cement requirement per cu. yd. with which to obtain the greatest strength possible can be computed, and that it is materially (at least 10 per cent) less than that used last season.

After our experimental experiences of the past in the design of concrete mixtures, I feel that tests should be taken in the field to determine the relative values of the various different types and brands of cement.

In conclusion, I wish to express my appreciation of the fact that I was allowed a small part in the cooperative studies of last year, and the hope and desire that these cooperative studies be continued during the coming season. Surely the benefits derived from field research are worth the investment.

Readers are referred to the JOURNAL *for December 1931, (Vol. 28) for further discussion which may develop. Such discussion should reach the Secretary by Nov. 1, 1931.*

Design and Operation of Central Mixing Plants

*Progress Report of Committee 603**

BY FRANK I. GINSBERG† AUTHOR-CHAIRMAN

The development of the central concrete plant as a commercial undertaking has been so rapid that there is yet scarcely time in which to have built up any "best designs" or "best operating methods" which are complete and comprehensive. It seems the proper function of the committee now, as Mr. Ginsberg has written, to outline recent progress, note some clearly developed pitfalls to be avoided and to stimulate discussion among the many active in plant design and operation. Several members of the committee participated in a symposum at the 26th Annual Convention, New Orleans, reported in this Journal March 1930, Vol. 26, p. 551. The present report prepared by the author-chairman has been submitted to the critic members of the Committee: Joseph E. Burke, Miles N. Clair, N. D. Crowley, G. L. Lucas, A. W. Munsell, H. F. Thomson, Fred C. Wilcox, all of whom give it general approval and some of whom expect to submit independent discussion. Mr. Ginsberg acknowledges his gratitude to the members of the committee for their general cooperation.—Editor

INTRODUCTORY

In the last three years there have been marked changes in the design of central plants due to the development of the ready-mixed concrete business, which has rapidly changed the picture in the manufacture of concrete. The primary purpose of this report is to outline progress in central plant design during this period, and second to develop discussion that will result in a

*Presented at the 27th Annual Convention, Milwaukee, Feb. 24-26, 1931.
†Vice-President, H. O. Penn Mach. Co., Inc., 140 St. and East River, New York City.

sound basis of control and the most economical production methods in the manufacture and delivery of central plant concrete. It is a far cry from the old haphazard methods of mixing concrete by the feeding of materials measured and controlled by the rule-of-thumb method, to the present precise mechanically controlled weighing devices and efficient material handling machinery. Much has been accomplished in this direction and the future developments in this industry will bring much more efficient methods in the control and the economic handling of central mixed concrete.

The conditions that will govern the design and arrangement of a plant for the production of ready-mixed concrete are controlled by a number of local factors. The location of the plant with reference to the possible consumption and use of concrete is important. The size and type of plant will of necessity be entirely controlled by these local conditions.

It is surprising to note that in towns with a population of 15,000 to 20,000 there have been as many as three plants in operation, all of which seem to be getting along successfully. This, however, is most unusual and is not generally practicable. There is, however, a potential outlet for ready-mixed concrete in small localities where there is considerable road work or street paving to be done, which may in some cases justify larger plants than really indicated by the more obvious conditions.

The method of receiving materials, whether by rail, truck or water, also controls the size and type of plant.

There has been considerable difference of opinion, whether the most efficient and practicable plant is to be the central mixing plant or the central proportioning plant.

TYPES OF CENTRAL PLANTS

The central mixing plant is one in which the materials are proportioned and mixed in a concrete mixer at the plant and delivered in agitating or non-agitating trucks to the point of final deposit.

At a central proportioning plant materials are all proportioned and batched into a mixer type of truck body, in which mixing is done enroute with water added to the batch in the truck, or mixed on arrival at the job.

Each type of plant has some advantages and from such tests as have been made at the time of leaving plant and the time of final deposit, there seems to be no appreciable difference.

There is also a design of plant recently developed which combines a central mixing plant and a central proportioning plant, and which is used for both purposes as occasion requires.

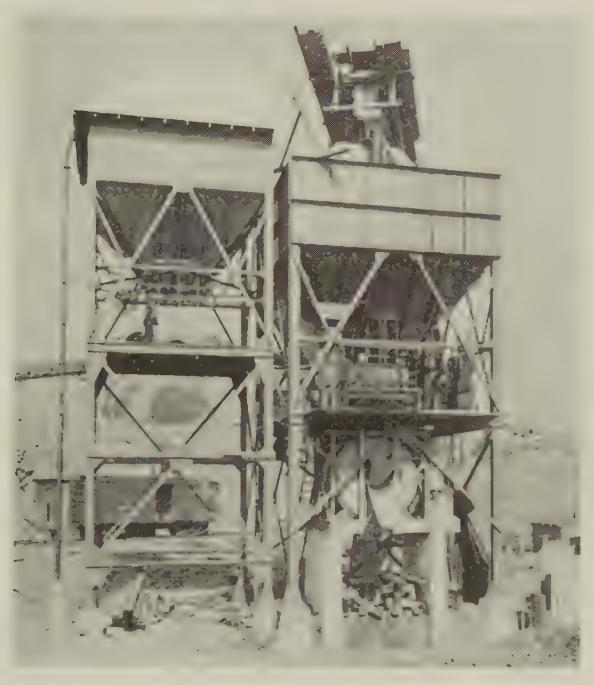

FIG. 1.—LOIZEAUX BUILDERS SUPPLY CO., ELIZABETH, N. Y.

PLANT EQUIPMENT AND METHODS

Bins. Steel bins have come into general use in nearly all types of central plants, and the weighing method of controlling the proportions of materials has supplanted the older methods of volumetric measurement. Material bins are generally divided for the storage of from four to six classes of aggregates and there are some occasions where storage of eight classes of materials has been provided for, but this is not usual.

Unloading Facilities. Where water facilities for receiving materials are available, the material is generally unloaded by crane or derrick directly into the bin. In some cases derricks are preferred to cranes because of the height of the bin, which ranges from 35 to 50 ft., depending of course, on the size and capacity of the bin itself. In under favorable conditions a crane unloads into a small hopper at the dock, and belt conveyors elevate the materials to storage bins. Cranes are faster in unloading where bin heights permit their use.

Conveyors deliver materials to a revolving spout on the top of the bin, which diverts the flow of materials into the proper compartment. The revolving spout is generally controlled from the platform, where the operator governs the proportions of the materials.

Where materials are delivered to the plant by rail the general method is as follows: Bottom-dump standard gauge cars drop the materials into a track hopper, from which reciprocating feeder or belt feeder delivers to a belt conveyor, thence to the top of the bin, and in some cases to a bucket elevator, or where conditions permit, the materials are delivered directly to a bucket elevator from the feeder, which in turn elevates the material to the top of the bin into a revolving type of hopper, from an extended chute at the top of the elevator. The unloading of standard gondola cars by derrick or crane clamshell bucket methods is also used extensively.

The vertical type of steel-enclosed elevator seems to have worked out best on permanent installations of this type. The choice of elevators is most important and the proper design of this unit and capacities must be given careful consideration. It is recommended that in large plants elevators have a minimum capacity of 100 cu. yds. per hour and be preferably, of the continuous type with double-strand chain and steel buckets; and that automatic brakes be installed against possible power line troubles while this unit is in operation.

Where the delivery of the materials must be made to the plant by truck, the general practice is: To arrange a form of grill work where the truck discharges the material directly into the boot of the elevator or into the hopper of a belt conveyor. There should be a gate on the hopper of the belt conveyor or bucket elevator

to permit control of the feeding of the materials on the respective units. In some instances, a long belt conveyor is used and the material discharged onto the belt conveyor through a series of gates. This is known as the tunnel belt method of storing and handling aggregates and is in successful use in a number of plants throughout the country. This belt runs horizontally under the stock piles and is then inclined to the revolving hopper on top of bin. The angle of this inclined section is generally from 18 to 20 deg. and in no case should this angle exceed 24 deg.

A method of delivering concrete materials in containers transported on gondola cars has been developed recently by some of the eastern railroads. The containers are open-top rectangular steel boxes, usual capacity about six tons, with twelve boxes on each car. The containers are of bottom-dump type; are handled by crane or derrick and can be used for sand, stone or cement.

HANDLING CEMENT IN BULK

The use of bulk cement is developing very rapidly, and suitable provision is being made by the manufacturers of bin and batching equipment so that the control of this material is properly coordinated with the control of the fine and coarse aggregates. There are a number of methods for handling bulk cement.*

One method is in delivery of cement in box cars or specially designed bottom-discharge cars from which cement is unloaded into hoppers through screw conveyors and elevated into cement storage bins. Cement from the storage bin is then handled by various devices such as screw conveyors, bucket elevators, into auxiliary storage bins directly over the cement weighing hoppers or by screw conveyors with electric push button controls feeding directly into a cement weighing hopper. It is suggested that in all cases where cement is being used in bulk, that it be delivered into a separate compartment for cement only after being weighed and then discharged into the mixer through properly arranged chutes.

There have been a number of instances of cement being weighed in the same hopper in which the aggregates have been weighed. This, however, is not recommended because the cement will build up on the wet surfaces of the aggregate weighing

*Committee 607, Use of Cement in Bulk. Herbert Coffman, author-chairman, presented a report at the 27th Annual Convention. It is scheduled for publication in the JOURNAL for Sept. 1931, Vol. 28.—EDITOR

hopper. The use of compressed air equipment for unloading and delivering cement directly into the cement storage bin is coming into more use and devices have been developed for unloading the cement directly from box cars or boats and pumping it into the storage bins without the additional use of power shovels or hand shovel methods that have been necessary in handling bulk cement to date.

The compressed air pumping system is widely and successfully used in the handling of bulk cement in central plants. Electric power is generally used for the cement pump and for the compressor unit. Automatic signal arrangements have been devised to show when the bins are full, to prevent overloading. It is well to have a supply of compressed air where bulk cement is being used, regardless of the method of delivery into the bins. This air supply is used for fluffing up the cement after the cement in the bins has settled and packed. The introduction of a small amount of air into the bin or container has the effect of causing the cement to flow more easily through the various valves and gates and eliminates much of the arching action over the openings of the bins and containers. Care must be taken to keep the air free from excess moisture. The use of specially designed cement gates is strongly recommended properly to control the flow of cement and also to prevent loss of cement through leakage.

Bins for storage of bulk cement should be properly designed and well constructed and made water-proof and leak-proof. The use of lead strips and lead gaskets in all bolted and riveted steel connections of the bin proper is recommended. The angle of the bottom slope should not be less than 55 deg. Roof may be of wood or steel and must be made tight and with necessary openings for easy loading in accordance with the method of delivering cement to the top of bin.

Bucket elevators and screw conveyors where used, should be dust-proof and water-proof, and with properly designed openings for cleaning; and for the adjustment of bearings and for replacements when necessary. Electric motors should be properly enclosed and protected against the elements and made dust-proof as far as possible.

Provision for the storage of more than one kind of cement should be given serious consideration. Two or three compartments are generally desirable with the proper arrangement of gates and diversion spouts for delivery to the weighing hoppers. Note: Bag cement is also successfully used in conjunction with bulk cement or separately where conditions warrant.

CENTRAL MIXING PLANTS—AGITATOR OR NON-AGITATING TRUCK DELIVERY

Proportioning methods in general use for the operation of wet plants, are practically the same as in central proportioning plants designed for the operation of mixing in transit. The weighing batchers should be at least 50 per cent larger than for the maximum batch to be weighed. There are a number of methods of measuring by weight.

1. The use of a one, two or three beam scale with electrically controlled quick reading weighing device.

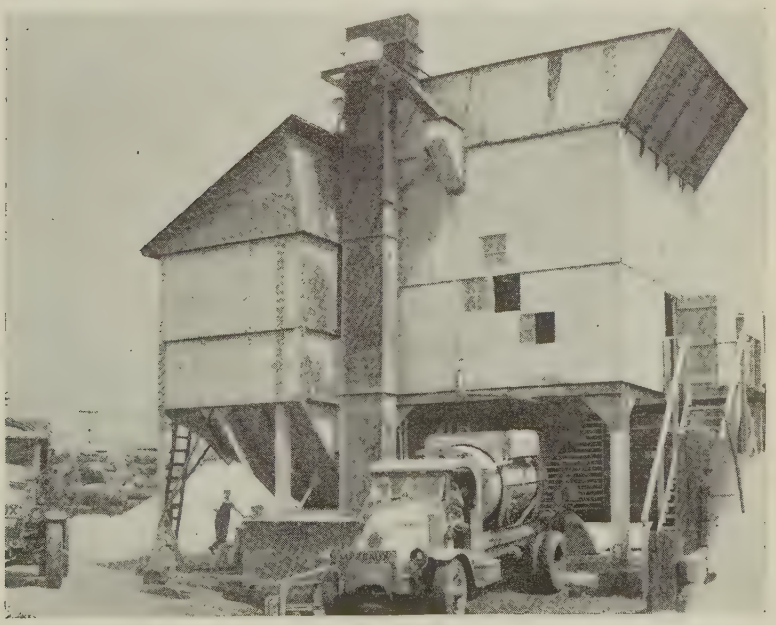

FIG. 2.—READY MIX AND SUPPLY CORP., ALBANY, N. Y.

2. One, two or three beam scales with indicator colored dial for quick reading purposes.

3. Large dial scale for weighing cumulative quantities, the various proportions being shown by indicators on the rim of the dial itself, and the total weight of all the materials representing the quantity in the batcher. The gates controlling the flow of the material into the weighing hopper are of two kinds—the sliding gate and the clamshell gate. The sliding gate is generally controlled by a rack and pinion arrangement with wheel controls, and the clamshell or radial gates are controlled with levers. It is important that the levers or wheel controls all be so arranged that the operator can control the various materials from one point on his platform. It is recommended cement not be weighed on aggregate material scales.

The tripping device for discharging the materials into the mixer are either of the direct trip or gate controlled discharge type.

The angle of the sides of the weighing hopper as well as the angle of the aggregate storage bin itself, should be of sufficient pitch so that the hoppers will be self-cleaning and not permit the arching of materials, which would necessitate pounding or hammering to accelerate the flow of material into the mixer. A 50 deg. angle is the flattest slope that is practical.

It is desirable that the size of the batchers be large enough to deliver a full batch to the size of the mixer used. The writer has observed in some plants the use of one yard batchers where a two or three yard mixer is being used. This necessitates two or three separate operations to measure one batch of concrete, with loss of time and economic inefficiency. There is also the possibility of error under such conditions.

Water tanks should be preferably of the automatic volumetric type or of the automatic weighing type. The automatic weighing type with electric controls is a practicable unit. There are a number of devices on the market that have been developed by various manufacturers for this operation.

The concrete mixers should be equipped with power discharge mechanism, within easy reach of the operator. They should also be equipped with a batchmeter and locking device such as is now in general use on paving mixers, so that the mixing time can be controlled properly.

The water pipe lines should be of sufficiently large size to permit rapid discharge of water into the mixer at the proper time. It is important that sufficient water enter the mixer to increase the mixing action and to prevent the building up of materials on the inside of the drum.

CENTRAL PROPORTIONING PLANTS—TRUCK MIXER DELIVERY

As previously stated, the operation of this plant is generally the same as that of the wet mix plant, with the exception that stationary mixers are not used, the material being charged into a truck body which mixes enroute.

THE COMBINATION PLANT

In this type of plant provision has been made for mixing at the plant and discharging into agitator type trucks, or proportioning for mixer trucks, or for dry batching materials for use in road pavers.

The general design of this type of plant is essentially as described above under "Wet Plants" but with by-pass arrangement controlled by the operator to divert the flow of materials into the central plant mixer, or directly into the truck mixer, or for loading batch trucks. The cost of the combination plant is very slightly more than that of the wet plant.

It is necessary to provide for heating the materials in the aggregate storage bin for cold weather operation. This is best done by live steam from a high pressure boiler with jets introduced into the lower section of the bin or with coils arranged inside the bin itself. The water used in mixing, must also be heated before passing through the water measuring tanks. The use of an auxiliary tank for heating and storing water is recommended to meet this requirement.

It is essential that devices be used in central proportioning plants to control the flow of materials so that the cement and various aggregates are fed uniformly into the opening of the truck mixer. This arrangement affords the advantage of a partial premix of the concrete materials and is a distinct advantage in the production of better concrete.

DELIVERY OF CONCRETE

Pre-Mixed Concrete, the Agitator, Semi-Agitator and Plain Trucks

After the sand, stone, cement, etc., have been deposited in the

mixer and been properly mixed, it is discharged into various types of agitating bodies.

1. The cylindrical drum type of agitator, is charged through a hatch at the top and the cylinder is revolved enroute to the job. This body is elevated or tilted by a standard truck hoist for the discharge of materials, through a rack and pinion tail gate. This unit is provided with an independent gasoline power plant for revolving the cylinder.

2. An open top agitating body has a central shaft with paddles attached. This type of truck is elevated by standard truck hoist to an angle of approximately 50 deg. and the discharge of concrete is by gravity and controlled by a rack and pinion tail gate. The agitation is controlled by power take-off gear arrangement from the truck engine.

3. A cylindrical type of body has blades on the inside either of the bucket type or of screw conveyor type, by which the material is propelled to the rear of the truck and discharged through rear control door. These units have an independent power plant for revolving the body. They require no hoist.

4. From another type the material is discharged from the bottom of a cylindrical body onto a pan where it flows by gravity to the rear of the truck.

5. A bathtub type of open top body has no agitator equipment of any kind, and the concrete is discharged in much the same manner as from the ordinary material dump truck.

6. The remixing type of open top body is intended to give a partial remixing action of the concrete when the body is tilted and discharged. This unit also has rear end control gate with rack and pinion arrangement.

7. Finally, there is the plain open-top, dump-truck body with truck-hoist and rear control, tail gates.

It is highly important that the concrete mixer be of the same capacity as the capacity of the delivery unit. This eliminates lost time and makes for general efficiency in the operation of the plant.

Truck Mixers

The equipment for this type of plant is practically the same as for wet mix plants, but with the addition of special loading devices designed to meet the requirements of the type of mixer truck

that is being used. Three types of truck mixers now in general use are as follows:

1. One type is a cylindrical body operated through a power take-off and gear drive from the engine of the truck. In this unit the material is charged into the cone-shaped body through an opening at the rear, and the proper amount of water added while mixing, enroute to the point of final deposit or after the truck arrives at the job. The water is measured at the plant and deposited into a tank having two compartments, one which contains the measured amount of water for the mixing of the concrete proper and the second smaller compartment which contains a small amount of water used in washing the truck out on its return trip.

The discharge of the concrete from this type of body is effected by the tilting of the body through a mechanical type truck hoist, the body revolving while discharging. While the truck is enroute to the job, the opening at the end of the drum is covered with a removable door to prevent leakage or loss of material.

2. Another type of truck mixer has a drum with a series of buckets and blades, and a discharge chute. This truck is charged at the plant through an opening in the top of the drum and the cover is then closed. Operation of the drum is by an auxiliary gasoline engine operating through a series of clutches to reverse the action of the mixing drum, for the purpose of mixing or discharging. This unit is equipped with a water tank properly calibrated, and the amount of water is added by the operator of the truck, in accordance with the required specifications. This tank has two compartments, one for mixing water and one for flushing or cleaning water.

The discharge of the concrete in this unit is effected by the removal of the cylindrical cover at the rear of the drum, and the introduction of a discharge chute similar to that used in the regular drum type concrete mixer.

3. Another truck mixer unit is also designed to be loaded through a removable cover at the top of the drum. This cover is closed when the unit has been loaded and the material is then mixed by rotating the drum. When the unit arrives at its destination, it is revolved in the opposite direction, thereby bringing the

material to the rear and discharging it through a cylindrical gate with wheel control.

This unit is also equipped with a calibrated water tank, the water being added by the operator of the truck to meet the required specifications. This design of truck unit with the interior blading arrangement similar to the screw conveyor, is equipped with an independent power plant and also with a power takeoff from the truck motor itself, with a series of properly designed reduction gears.

All of the above type agitator bodies and mixing truck bodies are built in sizes of one-to six-cu. yd. capacity and are generally mounted on trucks designed to carry the necessary loads. They are equipped with pneumatic tires and solid rubber tires, to meet local conditions.

There are various types of trucks now in use for this purpose, ranging from the regular four wheel trucks to the six wheel trucks, and the four wheel trailers.

The number of truck units necessary for the proper operation of the plant is determined entirely by the amount of concrete to be delivered and the length of haul. In some cases, a number of producers of ready mixed concrete have combined their operations in a manner that permits the transfer of a number of trucks from one plant to another, so as to take advantage of peak load requirements. This has worked economically in a number of instances.

MISCELLANEOUS PROBLEMS

In some plants individual problems have been solved by the ingenuity of the operators in devising special equipment and methods to meet the particular requirements of their local conditions, and it is safe to state that a majority of present plants are operating successfully but probably do not represent the ultimate development in plant equipment, plant control, or hauling and placing methods.

It is strongly advised that proper engineering control be set up covering all of the factors entering into the manufacture and delivery of central plant concrete. This should include proper inspection and testing service. Facilities should include the determination of proper concrete aggregates and their inspection. Suitable equipment should be provided at the plant for determining the moisture content of the fine and coarse aggregates,

and tests of this condition shall be made a number of times each day. Suitable engineering service should be available for the proper design of the various concrete mixtures required. Provision should be made for frequent inspection of all the measuring equipment used in the plant to insure constant accuracy.

There are a number of methods in use at the various plants throughout the country for records of maintenance costs, methods of keeping material receipts, delivery receipts, etc., all of which this Committee is assembling for a future report.

It is also desirable in all of these plants that contact be maintained between the office and the operator. This is best done through the use of a pneumatic system or some form of electric signal for delivering messages. The use of a telephone on the platform particularly in a wet mixed plant is not generally efficient, because of the noises from the mixer, motor, etc., which interfere with the clear hearing of the operator and result in misunderstandings. There are electric light systems that are used in some localities which have been effective in transmitting information from the office to the operator.

It is suggested that a machine shop be maintained at every plant where repair parts and replacements are carried for the truck equipment, and where necessary replacement items shall be kept on hand in case of wear or breakdown of any part of the plant itself. A few extra parts such as gears, chain, fuses, etc., will save their cost many times in the course of a year, by preventing shutdowns in the plant operation.

This report obviously is not complete but is intended to stimulate interest and discussion. There is in the hands of the Committee a considerable amount of detailed information in an incomplete state, which we will endeavor to compile and report on as rapidly as possible. Much research work is now being done along constructive lines and additional data on the subject will be submitted to the Institute in a later report.

Readers are referred to the JOURNAL *for December 1931 (Vol. 28), for discussion which may develop. Such discussion should reach the Secretary by Nov. 1, 1931.*

Specification for Concrete Burial Vaults

*Progress Report of Committee 709**

W. D. M. ALLAN, CHAIRMAN

INTRODUCTION

November 12, 1930, Wilber M. Krieger, executive secretary of the National Selected Morticians, wrote the secretary requesting that the American Concrete Institute prepare a specification which could be used to measure the quality of concrete burial vaults. At the same time Mr. Krieger wrote H. A. Ledyard, president of the National Concrete Burial Vault Association, outlining the value of a specification prepared by a national technical organization in extending the use of this product.

Department of Commerce reports show that the output of concrete vaults for 1929 was approximately 80,000 but members of the committee believe that actual production is nearer 125,000. The total vault business available for all types and materials is about one million per year. Even though the vault field is far removed from ordinary concrete work the satisfactory performance of the finished product depends upon the quality of concrete used. It is therefore proper that the Institute recognize the problem and comply with the request to develop, if possible, a satisfactory specification.

Attention has been directed by many vaults of poor quality and by the advertising of competitive types of vaults to the necessity for a standard specification. This led to the formation of Committee 709.

For nearly two years the National Concrete Burial Vault Association has had under consideration a specification for con-

*Presented at the 27th Annual Convention, A. C. I., Milwaukee, Feb. 24-26, 1931 by C. A. Wiepking, Testing Engineer, Milwaukee, Wis., member of the Committee. Other members of the Committee are: C. L. Berg, R. F. Hanneman, Prof. Carl Head, H. A. Ledyard, F. J. Mead, George M. Painter, H. G. Samson, J. H. Stuart and F. H. Van Ness.

crete vaults. Data collected by their research committee has been turned over to this committee.

In order to understand the quality of concrete required to make a satisfactory vault, it was necessary to study the problem from the standpoint of the funeral director, the cemetery superintendent and the manufacturer. The funeral director requires that the concrete be watertight, durable, strong, and dense enough to resist attacks of chemicals in ground waters. The cemetery superintendent demands the same factors but is especially interested in strength requirements which will eliminate sunken graves. The manufacturer requires a container of minimum weight that will meet the purchaser's requirements and which can be manufactured at a cost to compete with other types of vaults. The specification must cover all of these points and still be simple and easy to enforce.

Time has not been available since the formation of the Committee Jan. 20, 1931, to present a Tentative Specification. The Committee believes that this report should be on record so that discussion can be drawn from morticians and vault manufacturers on the provisions of the specification and the possibility of enforcement.

SUGGESTED SPECIFICATION FOR CONCRETE BURIAL VAULTS

1. GENERAL

Scope

1. This specification applies to reinforced concrete vaults, intended for use as burial receptacles, made in two pieces; a base and cover.

Basis of Acceptance

2. The acceptability of vaults shall be determined by the results of the strength, absorption and hydrostatic tests herein after specified, and by visual inspection.

Discussion—For well established plants with rigid methods of control, it is suggested that visual inspection and strength and absorption tests on cylinders should be sufficient to insure the quality of the vault, providing the purchaser is satisfied with methods for sealing at the grave.

2. MATERIALS

Reinforced Concrete

3. The reinforced concrete shall consist of portland cement, mineral aggregate and water in which steel reinforcement has been embedded.

Cement

4. Portland cement shall meet the requirements of the current Standard Specifications and Tests for Portland Cement of the American Society for Testing Materials.

Steel

5. Reinforcement shall consist of wire which meets the requirements of the current Specifications for Cold-Drawn Steel Wire for Concrete Reinforcement of the American Society for Testing Materials, or of bars which meet the requirements of the current Standard Specifications for Billet-Steel Concrete Reinforcement Bars of the American Society for Testing Materials.

Aggregates

(a) Fine aggregate shall consist of sand, stone or slag screenings, or other inert materials with similar characteristics, or a combination thereof, having clean, hard, strong, durable, uncoated grains and free from injurious amounts of dust, lumps, soft or flaky particles, shale, alkali, organic matter, loam or other deleterious substances. Fine aggregate shall be well graded and shall pass a ¼-in. screen. At least 5 and not more than 20 per cent shall pass a 50 mesh screen and at least 10 and not more than 20 per cent shall be retained on a No. 8 screen.

(b) Coarse aggregate shall consist of crushed stone, gravel, slag, or other approved inert materials with similar characteristics, or combinations thereof, having clean, hard, strong, durable, uncoated particles, free from injurious amounts of soft, friable, thin, elongated or laminated pieces, alkali, organic or other deleterious matter. All of the coarse aggregate shall pass a ⅜-in. screen and be retained on a ⅛-in. screen.

3. DESIGN

Minimum Design

9. The vaults shall be designed in accordance with the following assumptions:

(a) That the design load is equivalent to the vertical load uniformly distributed over the internal horizontal cross-sectional area of the vault and that the vault is likewise uniformly supported.

(b) The distance from the center of the reinforcement to the nearest surface of the concrete shall not be less than (. . . .) in.

Discussion—This dimension has been left blank because it depends upon the minimum thickness of vaults permitted. In general only one line of reinforcement is used so that this distance should be one-half the minimum thickness of vault decided upon.

(c) The shell thickness of the vault shall not be less than (. . . .) in.

Discussion—The shell thickness finally decided upon must consider the manufacturer's demand for minimum weight, yet provide for adequate protection for reinforcement and resistance to normal earth and water pressures. The Committee has not determined as yet whether this should be one inch, one and one-half inches or two inches.

(d) The minimum weight of reinforcement shall be equal to (. . . .) lb. per 100 sq. ft. of vault wall area and if of mesh shall have openings at least (. . . .) in. square.

Discussion—The average weight of reinforcement now used is approximately 50 lb. per 100 sq. ft. but individual manufacturers vary widely from this average. The opening in mesh must be large enough to permit the concrete to pass freely through and embed the individual members. The larger mesh also permits the use of heavier wires, is easier to handle and is frequently more economical. A minimum size opening 2 in. square and a maximum of 6 in. square are being considered.

(e) The net quantity of mixing water in the concrete mixture, including the surface water carried by the aggregate shall not exceed (. . . .) gal. per sack (94 lb. net) of cement. The proportions of aggregates to cement shall be such as produce concrete that will work readily in the form and around reinforcement without excessive puddling or spading and without permitting the materials to segregate or free water to collect on the surface. The slump of this concrete when measured according to the current Method of Test for Consistency of Portland Cement Concrete of the American Society for Testing Materials shall be not more than (. . . .) in.

Discussion—Experiments conducted over a period of two years at the Portland Cement Association Laboratory show that in thin sections (1 to 2 in.) with 7 days moist curing not more than 5 gallons of mixing water net should be used per sack of cement to produce concrete of unquestioned watertightness. The suggested maximum slump 4 to 5 in. is being considered to prevent segregation of aggregates and the tendency to form water pockets.

Placing Reinforcement

12. When a single line of reinforcement is used, it shall be placed in the center of the wall. The reinforcement shall be lapped not less than 30 diameters if of bars or 2 openings if of

mesh and securely tied with No. 18 annealed wire, or if welded the joints shall develop the full strength of the reinforcement.

4. WORKMANSHIP AND FINISH

Finish of Concrete

13. Vaults shall be smooth, free from stone, air or water pockets and structural cracks.

5. MARKINGS

Markings

14. All vaults made in accordance with this specification shall be marked as follows:

a. Meets current A. C. I. Specification

b. The name or identifying mark of manufacturer

6. PHYSICAL TESTS

Concrete Tests

15. The quality of concrete shall be determined by compression and absorption tests on 3 by 6-in. cylinders taken from the concrete used in making the vaults and manufactured and cured under identical conditions with the vaults.

Compression Tests

(a) When tested in accordance with the current standard methods prescribed by the American Society for Testing Materials, these cylinders shall have a strength of not less than (. . . .) lb. per sq. in. when 28 days old or when the vaults are delivered, if delivered in less than 28 days.

Discussion—The strength requirement has been usually considered as 4,000 lb. per sq. in., but since watertightness is a major factor in producing satisfactory vaults, it may be that in order to get the degree of watertightness necessary, the strength will be automatically increased to 5,000 or 6,000 lb. per sq. in. A higher compressive strength is also necessary if the thinner walls suggested in this report are adopted.

Absorption Tests

(a) At least three 3 by 6-in. cylinders in addition to those submitted for the compression test shall be furnished for the absorption test. The specimens shall be indelibly marked, to identify them with the vaults made with the same batches of concrete and cured in the same manner as the vaults.

(b) Specimens shall be dried at a temperature of from 100° to 110° C. (212° to 230° F.) for 24 hours.

Discussion—Laboratory tests show that 3 by 6-in. cylinders made of 5 gallon concrete and saturated at the beginning of the test will lose within 1.25 per cent of its total loss in weight with 24 hours drying at the temperatures specified. Since it will be only in prolonged rainy seasons in the case of vaults stored in the open that the specimen will be saturated, the 24-hour drying is considered sufficient. This is especially true, since the loss on drying at these temperatures for 24 hours will cause the concrete to lose more water than it would under any usual atmospheric condition. By decreasing the absorption requirement one per cent, the test for 24 hours can be corrected to equal complete drying.

(c) The dried specimens shall be placed in a suitable receptacle, covered with distilled water or rain water at room temperature (70 deg. F.) for 24 hours. After this immersion period, the specimens shall be removed from the water, allowed to drain for not more than one minute, the superficial water removed by a towel or blotting paper, and the specimen immediately weighed.

(d) The balance used shall be sensitive to 0.5 gr. when loaded with 1 kg. and weighings shall be read at least to the nearest gram. Where other than metric weights are used, the same degree of accuracy must be obtained.

(e) The increase in weight of the immersed specimen over its dry weight shall be considered the absorption of the specimen and shall be calculated as a percentage of the dry weight by the following formula:

$$\text{Percentage absorption} = 100\,\frac{\text{weight wet} - \text{weight dried}}{\text{weight dried}}.$$

The results shall be reported separately for each specimen.

(f) The average absorption shall not exceed (....) per cent for three (3) test specimens with no one specimen testing more than (....) per cent.

Discussion—It has been suggested that the average absorption limit should be placed at 3 or 5 per cent with no one specimen testing more than one per cent above the average agreed on.

Strength Test on Vaults

16. Vaults shall be tested with a load applied on top equal to (....) lb. per sq. ft. of inside horizontal cross-sectional area.

(a) The vault shall be set on a uniform bed of moist sand of such size that all of the particles will pass a ¼-in. screen.

(b) The top bearing frame shall not be allowed to come in contact with the top bearing plate. The upper surface of the sand

in the top bearing frame shall be struck level with a straight edge, and shall be covered with a rigid top bearing plate, with lower surface a true plane, made of heavy timbers or other rigid material, capable of distributing the test load uniformly without appreciable bending. The test load shall be applied uniformly over the top of the vault. (See Fig. 1.)

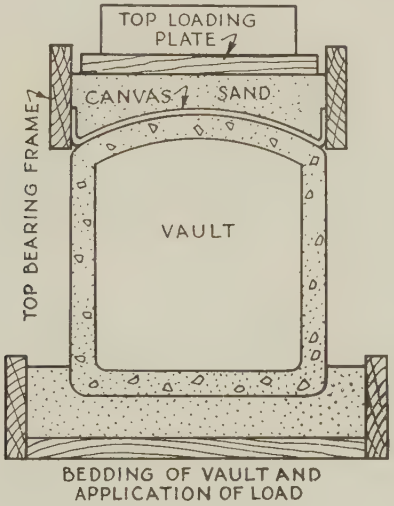

FIG. 1—SAND BEARING FOR COMPRESSION TEST ON CONCRETE BURIAL VAULTS

(c) The top and bottom bearing frames shall be made of timbers heavy enough to avoid appreciable bending by the side pressure of sand. The interior surfaces of the frames shall be dressed.

Discussion—The maximum puddled earth load on the vault in service is approximately 390 lbs. per sq. ft. of inside horizontal cross-sectional area but the committee believes that the test load should be increased to provide a factor of safety. Five hundred to six hundred lbs. per sq. ft. have been suggested. Field tests of vaults made under this specification will be made to determine what this load should be.

By using slabs of concrete having a combined weight equal to the required load minus the weight of the upper frame, sand and bearing plate, the test may be made very quickly on each vault sold or as required. Hydraulic jacks set up in rigid structural steel frames may also be used. (See Fig. 2.)

(d) After the load has remained on the vault one hour it shall be removed and the specimen inspected. The vault shall have failed if any visible structural cracks have developed during the test.

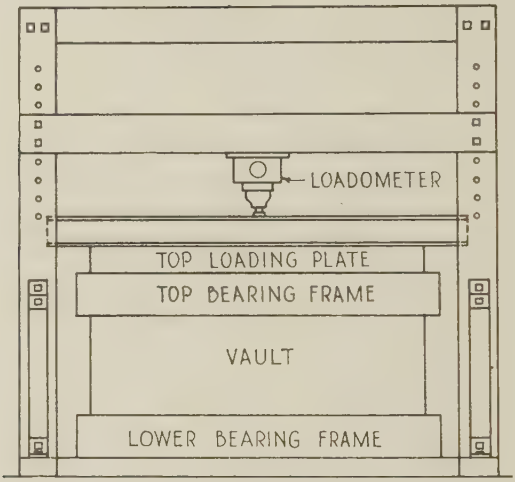

FIG. 2—SAND BEARING WITH LOAD APPLIED BY HYDRAULIC JACK

(e) At least one loading test must be made by the manufacturer each month but the purchaser may require one test be made for each (. . . .) vaults purchased.

Discussion—The strength of the test cylinders are a close indication of the strength of the vault manufactured according to this specification, and it is recommended that the purchaser accept the results of the single vault test made each month by the manufacturer together with the compression and absorption tests on cylinders as a measure of the vault strength. The suggestion has been made by some, that the purchaser be permitted to require one loading test for each ten vaults purchased.

(f) All vaults for testing purposes shall be selected at random by the purchaser or his representative from the stock of the manufacturer and shall be vaults which would not otherwise be rejected under this specification.

Hydrostatic Test

17.

Discussion—The method of making the hydrostatic test has not been developed to a point where agreement is possible. A concrete pit six feet deep in which the vault may be submerged and held down by a suitable weight or

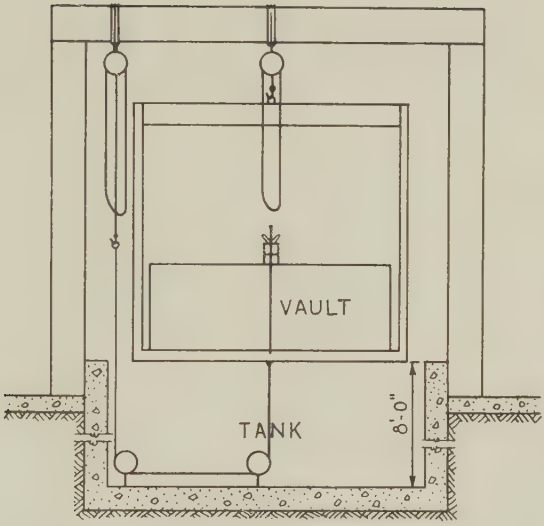

FIG. 3—HYDROSTATIC TEST BY SUBMERSION

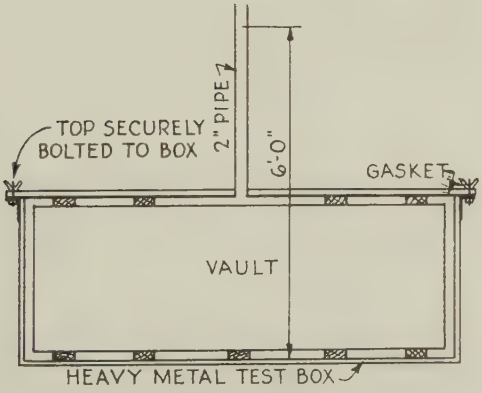

FIG. 4—HYDROSTATIC TEST BY PRESSURE BOX

system of winches has been used by a number of manufacturers. A rigid container equipped with a standpipe of suitable height in which the vault could be placed has the advantage of simplicity. A disc of suitable area, equipped with a two-inch standpipe, which could be fastened to the side of the vault is relatively cheap and easy to apply but has the disadvantage of not testing the entire vault including the seal. Discussion on this test will be particularly welcomed. (See Figs. 3, 4, 5.)

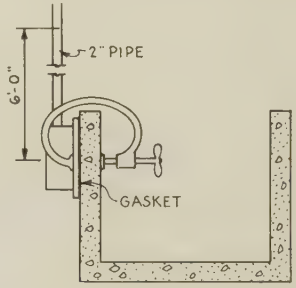

FIG. 5—HYDROSTATIC TEST ON SMALL AREA

Minimum Age for Shipment

18. Vaults will be considered ready for shipment when 28 days old, or when cylinder tests indicate that the concrete has attained the strength required.

7. SEALING

Materials and Methods

19.

Discussion—The Committee has not had sufficient time to investigate this subject and welcomes discussion by all interested parties. It has not, however, been definitely decided that this subject should be included directly in the specification. It will, of course, be included indirectly by the hydrostatic test.

8. INSPECTION

20. All materials, processes of manufacture and finished vaults shall be subject to inspection and approval by the purchaser or his representative.

21. Vaults shall be subject to rejection on account of the failure to meet any of the specification requirements.

END OF SPECIFICATION

The Committee presents its report in a form intended to create discussion and invites manufacturers, purchasers and interested engineers to review these requirements and submit their discussions.

Readers are referred to the JOURNAL *for Dec. 1931 (Vol. 28), for discussion which may develop. Such discussion should reach the Secretary by Nov. 1.*

Discussion of Report of Committee 203

"Cinders as Concrete Aggregate"*

CONVENTION PRESENTATION BY EINAR CHRISTENSEN, AUTHOR-CHAIRMAN

It makes me very happy that the American Concrete Institute has set aside this session for some of the problems of light weight concrete. It indicates that we are now in a position to spend some time on matters not pertaining to the dams and the beams and the arches and the roads that consume nine-tenths or more of our good cement—and can begin to consider the field beyond, which at present is small but which I believe will be of increasingly great importance.

Light weight concrete has been with us for some time—and I do not think anyone will question that it is here to stay. Whether the ultimate light weight aggregate is cinders (as they can be, and as I expect to see them prepared), or it is Haydite or some other natural or artificial cellular material, is something I do not know. Purpose, quality and economy must be considered. But I think that the lines of development have been laid out.

It should not be presumptuous to say that the cinder concrete industry took the early lead. It was through study of cinder concrete that we discovered that concrete might have other attributes besides those of strength and density. We began to hear about lightness, insulation, nailability, etc. I am not much wrong when I say that cinder concrete has been the step-child of the concrete industry. In saying that, I am not complaining. It is only during the last ten or twenty years that we have gotten down to fundamentals of rational design of stone concrete—and that has naturally and rightly kept the Institute busy.

*A. C. I. Journal, Feb. 1931; *Proceedings*, Vol. 27, p. 583. Mr. Christensen as Author-Chairman of the Committee made a presentation of the report at the 27th Annual Convention, Milwaukee, Feb. 24-26, 1931. Critic members of the Committee are: W. D. M. Allan, R. D. Bradbury, Miles N. Clair, Emil Praeger, M. J. Roach. The discussion here is incomplete and will be concluded in the December, 1931, Journal, Vol. 28.

It is my conviction that time is now ripe for a survey of our knowledge of cinders as an aggregate for concrete. The grand objection to cinder concrete has been that the material could not be put on a basis of rational design—but this is no longer true of factory-made cinder concrete, and it need not be true of job-made concrete. Perhaps we know a little more about the subject than some members think. It was to find out how much we know that Committee 203 was appointed.

It was really a big assignment—to cover the whole field from red hot cinders on the grate to the calm and presumably contented concrete in the structure. The result is in the February JOURNAL. As an easily read paper the report suffers from being much too long—as a comprehensive report it suffers by being much too short. Brevity is likely to be attained at the expense of some accuracy, which is most unfortunate, and it frequently leads to a confusion of opinion and fully established fact. How far we have avoided that in the report is something I cannot fully judge.

In reading the report, you will probably miss that favorite statement of many authors, that "more research is needed here, there and everywhere." I did not find it necessary to say that over and over again—the need for more research should be apparent to every reader. I also hope that the report shows that such research is not only needed but appears justified and deserved by what may be accomplished. I shall feel very much disappointed indeed if some of the opinions advanced in the report are not disproven or altered within the next ten years. But if the report can bring about such learning of new facts, then it has accomplished its main purpose.

In giving a brief synopsis of the paper I realize the difficulty of condensing these sixty-odd pages into ten minutes—particularly when considering the fact that the whole report as it now appears was a matter of considerable condensing. But I shall try.

Synopsis

Certain definitions are used throughout the report. For example, the term "Cinder Concrete" is applied only to a concrete made with an aggregate of nothing but cinders, while the term "Sand-Cinder Concrete" is applied to the type of concrete in which the aggregate is composed of both sand and cinders. "Cinders" is differentiated from "Ashes"—the former term applying to the residue from high temperature combustion of coal or coke, while the latter

applies as a more inclusive term, to all residues from the incomplete combustion of carbonaceous matter.

No differentiation is made between anthracite and bituminous cinders. While they differ in their physical character, they are both suitable for concrete when meeting the requirements here proposed for the raw material.

Cinders—The constituents of cinders affecting the value of the material as an aggregate for concrete are coal, coke, sulphates, sulphides, and (perhaps) lime.

The effect of combustible matter on fire resistance is surprisingly small. The Underwriters' Laboratories, in their present specifications for hollow concrete building units, state: "When cinders are used the average combustible content of the mixed fine and coarse aggregate shall not exceed 35 per cent by weight of the dry mixed aggregates." Bituminous coal of a certain character (having high absorptive power) may cause expansional movement during the early life of the concrete. A soundness test is described.

Cinders usually contain a small amount of sulphur compounds (sulphates, sulphides, etc.). Corrosion of steel in cinder concrete occurs only when the concrete is of such poor quality that air and moisture readily get into contact with the steel. Under the same conditions, corrosion will occur in concretes made with any type of aggregate. It is possible that in such concrete the corrosion of the unprotected steel will be accelerated by the presence of sulphates and the like in solution, but it is absurd to ascribe any effect as due to "oxidation of sulphides to sulphuric acid." The uniformly successful record of sand-cinder concrete in New York, as far as protection of steel is concerned, cannot be ignored.

Specification for Cinders—A specification for cinders should be liberal enough to be practical; otherwise it is not enforced. Based on this idea the report proposes a specification simply calling for cinders (not ashes) from high temperature combustion, well burned, free from foreign matter and so graded as to produce a cinder concrete meeting the strength requirements of the building code. Based on certain tests, limits for combustible matter and sulphur compounds are proposed.

Judging Cinders for Concrete—Judgment is still an important factor in making concrete, and when cinders are used as an aggregate it is well to have some simple rules for judging the material without having to resort to elaborate physical and chemical tests.

The report proposes certain rules. First, something should be found out about the source of supply; frequently records are kept there of analysis of cinders. Second, if the cinders contain rubbish they should not be used because the pile may have been a general dump and the cinders may contain dangerous impurities. Cinders from a chemical plant, it may be well to test with a water extract (boiled with distilled water) with litmus paper; the paper should turn slightly blue. Third, representative sample of the cinders should be dumped into a bucket filled with water; the fine ash and the lighter coke will float and the amount and nature of these may be judged. After draining the water from the bucket the appearance of the washed cinders should be compared with

that of the unwashed; the knowledge is gained of the relative amount of coke, coal, fines, porous, flaky, or fully vitrified clinker; the grading may be observed. Fourth, the strength of the larger particles may be judged by breaking them down. The weight per cubic foot should be determined.

The use of the bucket and the other simple methods proposed may appear very crude to the engineer—nevertheless, such simple methods have been found very useful, when used with some experience and common sense.

Testing Cinders for Concrete—When it is a matter of selecting a large and steady supply of cinders, a definite effort should be made to obtain the raw material from one known and reliable source. The cinders should then be subjected to more exhaustive tests, over enough time to determine average quality.

The tests should include determination of combustible content, nature of coal, soundness test of coal if bituminous, examination for impurities, sieve analysis, etc.

Making Cinder Concrete Building Units—The typical unit of the cinder unit industry is the 8 x 8 x 16 in. hollow block, containing two or three hollow cores, or from 30 to 40 per cent hollow space. Most specifications require this unit to have a compressive strength, at 28 days, of 700 lbs. per square inch of gross area.

Strength is not the sole criterion for quality of cinder concrete; the cellular structure should be developed in order to obtain such characteristics as lightness, insulation, nailability, etc. The resulting concrete should be considered within its own field, not as a general substitute for stone concrete.

Maximum size of aggregate is generally limited to ½ to ¾ in. Most desirable grading appears to be represented by a fineness modulus of 4.0 to 4.5 (maximum size ¾ in.). A simple rule suggests that the aggregate "split" 50-50 or 40-60 on ¼ in. sieve, assuming usual range from coarse to fine as found in crushed but unscreened cinders.

The voids of loosely packed aggregate appear to average about 55 per cent, with from 8 to 16 per cent inaccessible, sealed cells. A large amount of moisture is generally present in raw cinders when received. Damp volume is greater than dry volume, a bulking of about 25 per cent having been recorded, fairly constant within wide range.

Cinder concrete masonry units are made from a relatively dry mix, under pressure. It is well to bear this in mind when comparing the material with job-poured concrete; while machine made cinder concrete lacks plasticity, it is placed in such a way that homogeneity and the necessary density may well be obtained. Total mixing water necessary depends upon material and conditions. Tests are recorded representing best results at 1.5 to 1.8 gallons of water per cubic foot of aggregate (for 1:7 to 1:10 mix).

Open stationary-drum mixers are used. Conveyers for cinders are designed to minimize abrasive effect of material. Crushers of the jaw-type, slow-hammer type, or rolls are used in primary reduction; rolls are best for secondary reduction. Grading of cinders, while highly desirable, is at best an incomplete operation due to dampness of cinders and shape of particles. Only fast vibrat-

ing screens are suitable. It is important to prevent segregation of aggregate; this is attained by having storage bins of small diameter, keeping them full, or by dumping cinders in bulk.

Making Sand-Cinder Concrete—Sand-cinder concrete should be designed for the purpose for which it is used, and not according to arbitrary specifications like the "1:2:5" so frequently encountered. The main reason for the use of cinders in this type of concrete (structural concrete) is the lightness of the aggregate. The main reason for the addition of sand is to produce workability.

Tests indicate that blindly adding sand does not of necessity increase the strength or improve the quality of sand-cinder concrete; the grading of the combined aggregates must be considered. High uniform strength tests are reported on 1:2:5 and 1:2:4 sand-cinder concretes where the cinders had a fineness modulus of about 5.7, the sand about 2.4, and the mixed aggregates about 4.65.

In the same series of tests the total volume of mixing water (including that present in the damp cinders when received) measured about 13 to 14 gallons per sack of cement for the 1:2:5 mix and about 11 to 12 gallons for the 1:2:4 mix. The concrete was used in casting reinforced beams.

Recent tests indicate that cinder concrete without sand may give excellent results for structural purposes.

It is believed that there should be a considerable market for a prepared cinder, crushed and graded, and properly mixed with sand if necessary, to meet definite requirements. This may be the only way in which rationally designed mixtures may be obtained for structural purposes.

Characteristics of Resulting Concrete—The usual strength requirement for cinder concrete building units (hollow) is 700 lbs. per square inch of gross area. The compressive strength of standard 8 x 16 in. cylinders of good New York sand-cinder concrete is reported to be 800 to 1,000 lbs. per square inch at 28 days (1:2:5 mix), the modulus of elasticity is about 1,200,000 lbs. per square inch. Much higher results are obtained under conditions of better control than that usually found on jobs at present.

The average weight of cinder concrete, as used in the cinder unit industry, appears to be about 85 to 90 lbs. per cubic foot. 1:2:5 sand-cinder concrete (structural concrete) averages about 110 to 115 lbs. per cubic foot.

When comparing absorption percentages with those of stone concrete and other heavier building materials, consideration should be given to the lightness of cinder and sand-cinder concrete. The significance of the usual absorption test is questioned. The test does not seem to give information regarding resistance to weather and freezing, capillary behavior, etc. The shape, size and distribution of pores should be studied.

The fire resistance of well made cinder and sand-cinder concrete appears well established. The behavior under exposure to fire and water is remarkable; the heat transfer is low when the cellular structure is properly controlled.

Data on cinder concrete (as used in making cinder units) indicate the Coefficient of Conductivity "K" to be 3.33 (per inch thickness). For usual

conditions, an 8 in. hollow cinder block wall (exposed) will have a Conductance (C) of 0.45 or less, and a Transmittance (U) of about 0.34.

Exposed surfaces of cinder concrete appear to have a very high sound absorption. The sound transmission through properly constructed walls of cinder concrete appears low. As with heat transmission, the cellular structure is the determining factor.

Properly made cinder concrete will receive and hold nails, and woodwork is nearly always nailed direct to the masonry wall. Machine made (relatively dry mix) cinder concrete building units have an interesting surface texture offering remarkable adhesion for plaster, mortar and the like.

Such is our report on an aggregate that some able engineers use to the extent of millions of cubic yards, while other able engineers flatly condemn it. They did not wait for this review to build the Empire State Building, the Chrysler Building or all the other buildings that have given New York its vertical growth, and in which so many thousand yards of cinders were used. I don't think the report will make them regret it. Rather, I hope the report will lead to an increasing and an increasingly intelligent use of cinders as an aggregate for concrete.

In getting up the report I have received great help from the members appointed on Committee 203. In this respect I am probably much more fortunate than some other author chairmen—and I am very grateful.

WRITTEN DISCUSSION

BY GEORGE E. STREHAN*

The author's proposed definitions of "cinder concrete" and "sand-cinder concrete" are not in line with engineering practice and in the writer's opinion are misleading. Portland cement concretes are generally designated as "stone concrete," "slag concrete," "gravel concrete," etc., as determined by the coarse aggregate. The discussion advanced in the report does not warrant a change from this practice. In the writer's opinion, what Mr. Christensen refers to as cinder concrete in the "factory-made cinder unit" of today is not well-made cinder concrete at all. Plasticity, workability and durability are generally required essentials of good concrete. Plasticity depends upon the presence of a sufficient quantity of plastic paste to form a homogeneous

*Consulting Engineer, New York City.

mixture with the coarse aggregate; workability determines the ease of combining and placing the mixture without excessive voids, honeycombing or segregation; and durability in concrete construction exposed directly or indirectly to the elements is in large measure dependent upon the absence of porous or cellular structure.

The two controversial features connected with the use of cinder concrete, whether in the form of precast shop-made units or monolithic, poured-in-place concrete are: (1) corrosion of reinforcement; and (2) durability. The writer would dismiss all discussion of the fire resistance of cinder concrete as having been demonstrated without a margin of doubt both in practice and laboratory experience. The controversies as regards corrosion of embedded steel and the permanence of cinder concrete are however, exceedingly live subjects; and are due to the *misuse* of cinder concrete rather than to any inherent defect of the material itself. The author refers to the excellent behavior of the cinder concrete construction in Professor Woolson's test house erected in 1905 at Greenpoint, Brooklyn, which is still doing duty as a test furnace after some 300 to 400 hours of 1700 deg. F. fire. The walls of this structure were made of a 1:2:5 plastic mix of sand, cement and steam boiler plant cinders quite different from the concrete generally employed for cinder block units.

Mr. Christensen speaks with authority on the subject of the shop-made cinder building unit. He is concise and thorough on the subject of selection of proper cinders for pre-cast units. His seven rules of procedure to determine the quality of cinders for use as an aggregate should provide a good measure of the quality of the material for aggregate purposes in present day practice. The requirements of practical value are maximum permissible combustible content in the cinders (now fixed by the Underwriters at 35 per cent), and minimum concrete strength requirements for use of the unit for either load bearing or non-load bearing purposes. The discussion of the manufacture of cinder units is thorough in detail and presents an ideal for the industry. The fact remains however that to the average block-plant, cinders that can be bought for 50 cents a yard are vastly more attractive than cinders costing $1.40 a yard for fixed grading and correct chemical composition. One very important considera-

tion is not stressed sufficiently by the author. The machine-tamped cinder concrete unit is made of a relatively dry, non-plastic mixture. Sufficient water cannot be added to the mixture for complete hydration without encountering the possibility of slumping of the block. The curing conditions prevailing in most cinder concrete products plants are not conducive to complete hydration. Accelerated or steam curing is seldom resorted to. A liberal use of calcium chloride is a frequent substitute used to accelerate setting. The author states that "Because of the porosity of the cinder aggregates, a large water reserve is available for hydration of the cement, and because of the nature of the concrete, the water is slow in reaching the surface where it evaporates." This is contrary to the writer's experience. Because of the physical characteristics of the aggregate, the excess water in the block has a tendency to rapid drainage.

It is known that well-made plastic concrete deposited on the interior of a building exposed to extreme dry heat will lose strength in time, through the arrested process of hydration caused by the absence of the necessary moisture content. It is the writer's belief that very little study is given to the control of water content in the average cinder unit plant; and frequently the only water used in manufacture is the water contained in the cinder aggregate as stored amounting perhaps to 4 or 5 lbs. of water per cubic foot. The uncured cinder unit placed in the wall continues to hydrate for a considerable period beyond the conventional 28 days, accompanied by volumetric changes that are always incident to this continued "working." This process plus the cellular character of the block unit, in the writer's opinion, accounts for much of the lack of durability or permanence in the structure as well as the corrosion of embedded steel occasionally demonstrated by the rusting of nails driven into the masonry. Moisture absorption is particularly large in cinder mortars and in masonry walls, the cinder concrete building unit is not fully protected against the moisture forced in from the outside. The ultimate curing and hydration of the cement content in the block is dependent on the acquisition of this moisture. The high expansional movement of cinder concrete normally associated with its early life is very likely to be prolonged to the

masonry in the wall because of the slow hydration of an all-cinder concrete mixture.

The second sub-division of the paper dealing with the practices and uses of "sand-cinder concrete," has failed to emphasize some of the true significance of cinder concrete proper, particularly as it relates to New York experience. From 1896, when this type of construction first received recognition in New York City, after full-size fire and load test investigations by the New York Bureau of Buildings, until 1915, the industry has been continually experimenting with various proportions of sand and cinders and of cinders alone in combination with portland cement. Much of this research was done prior to the publication of the "water-cement ratio" and the "fineness-modulus" theories. Nevertheless the development of the 1:2:5 sand-cinder mix is not an arbitrary choice. It was arrived at by the same methods as the 1:7 and the 1:9 cinder mixes of the block industry; and proved its effectiveness as a fire-resistive concrete of sufficient strength and density combined with relatively light weight. It was found that the run of commercial cinders resulting from forced draft burning is generally deficient in fine material and that the cinder fines are of such nature as to resist combination with the cement and water. In a batch, the mixture results in a harsh, unworkable concrete. Some of the earlier approvals granted by the City of New York included mixtures of 1 cement to 5 or 7 cinders. In general, however, these harsh mixes have been abandoned. Moreover, sanding not only gives a more workable mixture but actually shows greater economy in cement yield. Another difficulty which developed with the use of a graded cinder aggregate is the tendency toward segregation of fine and coarse aggregate in transportation and handling. The addition of a silica sand to the mixture was found to be a practical solution of the problem.

Though the introduction of sand to commercial cinders increases the weight of the concrete, it is generally accompanied by increased strength. The author has cited some figures to prove the contrary. The conclusion drawn from the investigations at Columbia University for the New York Bureau of Buildings as reported in Vol. LXXIX, Transactions of the American Society of Civil Engineers was that 800 lbs. per sq. in. is the

minimum compressive strength desirable or necessary to develop the safe load capacities of floor slabs as determined by the empirical formulas developed from these tests. The investigators were not aiming at 800 lbs. per sq. in., but determined that this strength could be practically attained and was sufficient for the purpose of providing an economical, fire-resistive floor filling between structural beams and girders, with an economical cement factor. Higher strengths can be and have been secured by modern control methods; but are economically impractical in application to the short span floor construction. With the modern demand for minimum story heights and maximum number of stories in a given height, there is a tendency toward the use of longer span floor constructions typified by the two-way reinforced slab supported on four edges. The writer believes that the use of a light-weight controlled cinder concrete mixture will be highly desirable for this use, and that further research for this purpose may be required along the lines of controlling the cinder aggregate.

To demonstrate the quality of concrete possible with New York materials and methods, the following observations might be cited. The cinder concrete made on the unsupervised job, as determined by job cylinders of presumably a 1:2:5 mix averaged from 500 to 1000 lbs. per sq. in. compressive strength. Job cylinders made from the same component materials over which the investigators had absolute control of the proportions, produced strengths of 1100 to 1500 lbs. per sq. in. Laboratory cylinders of the same component materials in a 1:2:5 mixture gave strengths as high as 1700 lbs. per sq. in. at 28 days. These data are reported in the paper above referred to. More recent tests on cylinders from jobs in New York City show strengths of 1:2:5 sand-cinder concretes as high as 1300 to 1500 lbs. per sq. in. and the same component materials mixed under laboratory conditions developed strengths as high as 1750 lbs. per sq. in. These values compare very favorably with Dr. Humphrey's results of 1000 to 1200 lbs. per sq. in. for the 1:2:5 and 1500 to 1900 lbs. per sq. in. for the 1:2:4 sand cinder concretes. These too are laboratory results. The amount of mixing water is not reported in the paper for the New York material, but this in general, to the writer's recollection, averaged 12 to 15 per cent by weight of the combined dry mixture or approximately 10 to 12 gals. of

water per sack of cement. Water content was carefully noted in the laboratory specimens and the records probably still exist although not available at the moment of writing. The field specimens were not under the control of the investigators and were purposely selected to represent commercial practice.

By reason of the nature of the poured-in-place construction, any cracks that develop from the volume changes take place along the natural cleavage planes furnished by the enclosing steel frame. The concrete being poured with sufficient water content to give flowability and to coat the embedded reinforcement with cement mortar hydrates sufficiently in the first few months of its life. Thereafter there is little moisture change on the interior of the average occupied building, and consequently little further volumetric change. This is not true of the factory-made, dry cinder unit which is cellular in nature, highly fire-resistant, but purposely manufactured to give a rough surface texture for architectural and ornamental treatments, if in any way subjected to the elements.

The need of a smooth-faced sand in the plastic poured-in-place cinder concrete is quite evident to anyone who has had experience with this aggregate. If more cinder fines are added to the mixture to produce workability, the cement factor becomes uneconomical. In the cinder mix without sand, the water fills the voids of the coarse aggregate and carries some of the cement with it into these cores. The cinder fines do not combine with the cement to form a plastic mortar. The general appearance of the mixture is a mass of coarse unattached particles which are harsh in appearance as well as in working qualities. When the mix is allowed to stand, the water drains out of the cell-like structure of the aggregate and is lost. The addition of the smooth-surfaced particles of sand forms with the cement a plastic matrix which coats and binds the coarse aggregate together. Unlike the cinder fines, the sand tends to hold the water in suspension where it can combine freely with the cement particles.

The writer agrees with Mr. Christensen that there is an extended field for the use of properly controlled sand-cinder concrete, such as for long-span floor constructions. For such usage, further investigation is required to determine the correct water-cement ratio and grading of fine and coarse particles. Cinder

aggregate is generally cellular rather than porous in character and requires a cementitious paste to close these voids and bind the particles together. An excess of cement would accomplish this purpose in a cinder mixture, but not as economically as additional sand in a sand-cinder mixture. The former is a lighter-weight product but lacks the properties of a good concrete.

In connection with the development of a controlled aggregate for light-weight concrete, made by submitting ordinary house ash to a smelting process whereby most of the combustible constituents of the ash are consumed and the non-combustibles are fused into a hard, vitreous clinker of iron-aluminum silicates, and then crushed, screened and graded to a predetermined sieve analysis, an extended investigation was made of the sizing of particles and proportions of fine to coarse aggregates required to produce a practical and workable concrete mixture. This research was done at Columbia University by John S. Peck, Testing Engineer, and the writer has requested Mr. Peck to submit a digest of his findings as a contribution to this subject. The aggregate resembles cinders in many respects, contains about 50 per cent voids, and presented similar problems in the making of concrete, in that an economical, workable concrete could not be produced without sanding the mixture.

BY JOHN SANFORD PECK*

The writer recently spent considerable time on the problem of developing a workable and commercially practical mix using a manufactured material that was projected for use as a light weight aggregate. It was in effect a synthetic cinder.

Very illuminating results developed from this work, and indicated the fallacy of a generally accepted theory. In the writer's opinion, the fineness modulus is of little use in designing concrete mixtures. It is outworn and discredited by the latest practice.

The writer found that minor variations in the grading had no effect on the strength of the concrete. A pinch more or less of one size or another represented wasted effort. The only thing that did affect the result was the relation between the volumes of coarse and fine aggregate in the mix, calling all material

*Assistant Engineer of Tests, Dept. of Civil Engineering Testing Laboratory, Columbia University.

coarser than ¼ in. "coarse aggregate" and all passing ¼ in., "fine aggregate."

The condition necessary for maximum strength plus maximum workability was, that there should be present enough mortar i. e., fine aggregate and cement, to fill the voids in the coarse aggregate and a little excess to promote workability. In this statement the writer is sustained by no less an authority than Professor Talbot of the University of Illinois in his work on the mortar void theory.

The writer started with a grading that was made up in the laboratory to approximate closely Fuller's Curve of Maximum Density. Call this Grading No. 1. When this mix was tried it was obviously lacking in fines and therefore grading 1A was made up by adding fine aggregate until the ratio of fine to coarse was 1 to 2 by volume. Grading 1B was also made with a fine-coarse ratio of 1 to 1.5. A third grading was made in which the fine-coarse ratio was 1 to 1. Using a real mix that gave a constant cement factor of 5½ bags of cement per cubic yard of concrete, and with all other factors equal, these gradings gave the following results:

Grading	Fine-Coarse	Compressive Strength at 28 Days Lbs. per sq. in.
1		1523
1A	1 to 2	1852
1B	1 to 1.5	1957
1C	1 to 1	1883

These results show that the mix most efficient in strength was one with the fine-coarse ratio of 1 to 1.5. In the writer's opinion, the slump cone does not show workability and to date no acceptable quantitative method has been developed. The workability therefore was judged, not by the slump cone but by the general characteristics of the mix, its "fatness," and the ease with which it could be rodded into the cylinder mould. Grading 1 had no workability at all. It was harsh and rebellious. Grading 1A was not much better, but grading 1B gave a near approach to plasticity and grading 1C gave a true plastic mix.

Mr. Christensen is closer to the real answer to the problem when he speaks of splitting cinders as received on a ¼ inch screen

and recombining on the basis of required strength and workability. The average run of commercial cinders as used in New York is too harsh and lacking in fines to produce either strength or workability and the use of sand to supply that lack is more economical than screening and recombining the cinders to secure the proper proportions. It is the logical conclusion, and experience has amply proved that the 1:2:5 sand-cinder mix fulfills the requirements.

Tens of millions of square feet of sand-cinder concrete construction have been installed in New York City and in no case has fire collapsed a single arch nor has failure occurred where the slab has been in place more than 30 days. To crush or screen the cinders which form such an important part of this construction would be to load up an efficient construction with an expense that would not be justified.

BY E. H. PRAEGER*

All of the many different building materials now available may be used to advantage in the proper place. The author of this report, although actively connected with the production of cinder concrete materials, calls attention to the fact that, while cinder concrete has many virtues, there are conditions under which it may not be suitable.

Cinder concrete has been used as a building material for some thirty odd years. It was developed as a fire-proof floor system and approved in New York City after a series of tests. During the first 10 or 15 years, many tests were made and there was considerable discussion both by those who favored and those who opposed cinder concrete as a floor construction. In the last 10 or 15 years, however, the subject seems to have been forgotten.

The pre-cast cinder concrete unit is of more recent origin, it having been developed as a block for partitions and load-bearing walls for light construction. In some localities these blocks have been used for exterior walls with only a coat of cement paint to act as a water-proofing agent and some very pleasing architectural results have been obtained. Where storm conditions are more severe, this method is not suitable and it becomes necessary to use stucco, brick or stone as a facing material. Recently pre-

*Critic member Committee 203; Consulting Engineer, New York City.

cast cinder concrete lintels have been developed in connection with the use of cinder concrete block construction. A still further development is the use of cinder concrete for pre-cast floor joists. These joists are installed in a manner similar to wood joist construction. The investigations to date seem to warrant a future for this type of construction for light floor loads in places where cinders are available.

The author has covered the subject of cinder-concrete, especially in regard to pre-cast units, in an extremely comprehensive manner. There has been considerable prejudice against cinder concrete at different times, but most of this is probably due to ignorance, and the publication of accurate scientific data and results of tests should help to clarify the existing hazy atmosphere. Recently, the writer was called in by a newly elected mayor at a formal meeting of the school board of a suburban town to advise as to tearing down and rebuilding a new one-story school, then well under construction, because the contractor had used cinder blocks in backing up his brick facing. There had been so many rumors concerning this material that the parents were extremely skeptical about permitting their children to attend school if this alarming condition were not rectified.

It is not surprising, however, that erroneous impressions may exist among laymen, when it is realized that the engineer, even now, has comparatively few data in regard to cinder concrete as used in floor construction. Furthermore, this condition is not helped by those who specialize in other somewhat similar materials and who emphasize the faults in cinder concrete, many of which may or may not exist. Some of the criticisms of cinder concrete are admittedly justified, others are not. This material was developed as a substitute for brick, terra-cotta and stone concrete floors and the questions of fire resisting qualities, corrosive effect on metal (structural steel, reinforcing steel and pipes), permanency, strength, weight, economy, design, manufacture and installation have been discussed at length.

In regard to fire-resisting qualities, laboratory and actual fire tests have demonstrated that a well mixed cinder concrete is at least the equal of any fire-proofing material which may be used in a similar manner.

In regard to corrosion of steel, investigations have proved that the greatest part of the criticism from this source is unjustified. Evidences of corrosion have been noted, but in most cases the cause has been traced to faulty materials or workmanship. In order to obtain the most satisfactory results with cinder concrete, the design, materials and workmanship must be of a high order. It must be admitted that the above requirements do not always exist and our best efforts should be exerted towards improving this condition. The investigations of the author should dispel the overworked and unwarranted fear of the effects of sulphur that may be contained in the cinders. The following paragraph from an article in the *Builder* (England) under date of September 12, 1930, illustrates a very recent English viewpoint.

> Clinker concrete should never be used to cover steel nor be reinforced, on account of its porosity and probable presence of sulphur in the clinkers.

In cinder fill pipes and conduits should be covered with cement mortar before the fill is placed, but in this case the conduits need not be of galvanized metal except in special instances.

As to permanence, we can only state that many square feet have been in place for over a quarter of a century and give no evidence of deterioration. There should be many excellent opportunities for testing actual installations to destruction, as several fire-proof buildings with cinder concrete floors have been demolished and certainly many more will come down in the near future, in order to provide room for more up-to-date buildings. Extensive tests of old slabs in these buildings would give a truer indication of the characteristics of this construction than isolated laboratory tests.

The compressive strength of a uniform run of cinders can be determined, but this may not be relied upon as an accurate comparison of what may be expected in the floor slab as installed in the building, as results of field tests have varied by more than 100 per cent as compared to laboratory tests. The fact that cinder concrete is not as strong and as dense as stone concrete may be an advantage in light manufacturing buildings, the various sections of which may be subject to local vibrations. Such vibrations will be absorbed within a small area and not transmitted throughout the entire structure as would be the case with stone concrete.

As cinder concrete weighs only about 70 per cent as much as stone concrete naturally this fact has a considerable bearing on the tonnage of structural steel as well as on the cost of foundations of a tall building.

As to economy of the structure compared to other systems, this is dependent upon the location of the job and the conditions of the market. When structural steel is low and where cinders are available, it is difficult for any other fire proof system to compete with cinder concrete floors. In the middle west reinforced concrete framed buildings, of the apartment house type, are considerably cheaper than steel-framed buildings with concrete floors, but in New York City steel framed buildings with cinder concrete floors are more economical than any other type of fire proof construction.

There are probably more unknown factors in regard to the design of so simple and yet so important a member as cinder concrete slabs than exist in the design of some of the most complicated engineering structural members. In some localities cinder concrete is designed in accordance with the usual theory of flexure, using about one-half the stress allowed for stone concrete and several other assumed values of constants. In New York City no mention is made of the stress in the cinder concrete but empirical formulae are used to determine the area of reinforcing for different loads, spans and conditions of restraint. These formulae are based upon the results of laboratory tests, which tests are often quite unlike actual job conditions. Whether the concrete acts as a slab, as a flat arch, as a filler between the reinforcing which is in suspension, as a combination of any or all of the above, or whether or not it acts at all, are questions that have not been satisfactorily answered after many years of extensive use of this material.

The fact remains that in different cities entirely different requirements obtain as to the design of cinder concrete slabs. These different requirements give results which cannot be compared, the empirical formulae permitting loadings which in some cases would stress the materials beyond their ultimate strengths as determined by the usual concrete formulae. The empirical formulae were deducted from tests, and the fact that other than

slab action exists is self evident. However, the question of design should receive further study and tests should be continued until we arrive at results which will check with some theory or combination of theories. At this time, to cite only one example, New York City would permit a superimposed load of 400 lbs. per sq. ft. on a 4 in. cinder concrete slab on an 8 ft. span provided 0.36 sq. in. of reinforcing mesh were used per foot of width. For this span and equivalent total load, Los Angeles would require a 6 in. stone concrete slab with 0.46 sq. in. of reinforcing rods. According to the usual concrete formula, the compressive stress in a 4 in. stone concrete slab with this span and load would be 1200 lbs. per square inch. It probably is fortunate that floors are seldom loaded to their full design loadings and it is my opinion that the present empirical formulae are too optimistic and should be made more conservative.

Attention may here be invited to the fact that cinder concrete slabs, which also encase the supporting steel beams in the usual manner, materially increase the strength of these supporting beams and girders. A very complete series of laboratory tests has recently been conducted under the auspices of the Western Society of Engineers, in which cinder concrete and gravel concrete slabs, supported by steel beams (some of which were encased in concrete and others were not) were loaded with several different loadings and readings were taken and recorded. The stresses and deflections of the supporting steel beams and girders were measured by a strain gage and a deflectometer. These quantities were then computed by the usual formulae and the results tabulated as percentages of measured to computed stresses and deflections. These comparisons clearly show the assistance rendered to the structural steel by the concrete fireproofing, especially at design loads. The concrete acts as a stem of a T beam, thus increasing the compression area and raising the neutral axis. Whether or not the same results may be expected with average job conditions is a debatable question. However, as a result of these tests the committee unanimously recommended 24,000 pounds per square inch as the allowable unit stress in structural steel I beams up to 24 in. deep when properly encased in either stone or cinder concrete. Incidentally, the committee recom-

mends the adoption of the empirical formulae for cinder concrete now in use in New York City.

The manufacture and installation of cinder concrete is probably even more important than the question of design. We are living in an age of specialization and while this often proves an advantage, it sometimes has the opposite effect. Cinder concrete is a separate trade and this work is rarely performed by the general contractor. Although the materials are defined in the specifications and the proportions, time of mixing, method of placing, etc., clearly and carefully covered, these requirements are seldom adhered to rigidly. Recently, a reliable cinder concrete contractor, on signing a contract with a general contractor from a near-by city, stipulated that his quotation was based upon his being permitted to install his work without interference by the general contractor. This sub-contractor had no intention of purposely "skinning" the job but he knew that the general contractor was familiar with stone concrete and unfamiliar with cinder concrete installation and rather expected him to be somewhat shocked at the comparison. There seems to be an unwritten law that as far as cinder concrete is concerned, almost anything will do. The specifications for cinders, as proposed by the author, are a step in the right direction, but specifications alone do not insure results. When a load of cinders is dumped in the hopper to be used a few minutes later, it is too late to check up the specifications. The answer of the material man is that they are the best he can get right now, and it is either a case of take what you can get or nothing. There is plenty of room for improvement on the job in regard to careful proportioning of the materials, time of mixing, quantity of water, method of placing and other job conditions. The material is generally mixed in the basement in a continuous mixer and neglected from the time it arrives as raw materials until the forms are stripped. If the designated size of mesh has been stretched over the steel beams, it does not seem to make much difference what location in the thickness of the slab the mesh is placed. Failures have been few but there have been some and it is believed that a more rigid control of job conditions will materially improve the finished product at a very small additional expense.

The possibilities of painting and decorating cinder concrete

directly, thereby saving the cost of lathing and plastering has been given some study and there have been several jobs where the results have been quite satisfactory when sufficient precautionary methods have been taken.

The field tests suggested by the author should be included in the specifications of all important jobs and test cylinders should be taken frequently if for no other reason than the psychological effect on the workmen. Exact proportions of mix, preferably not less than 1:2:4, should be insisted upon. Sieve analyses can readily be made as hand sieves are inexpensive and accurate enough for job control. The quality and uniformity of the cinders can be guaranteed if the engineers insist.

A step in the right direction would be taken if some of the factory methods of manufacturing cinder concrete units were transposed to the job.

BY EINAR CHRISTENSEN

Mr. Strehan opens his discussion with the statement that "the cinder concrete in the factory-made cinder unit of today is not well-made cinder concrete at all." This is decidedly contrary to the writer's experience, and does not appear to be in any way proven by the arguments advanced by Mr. Strehan.

It should be borne in mind that while the mixture used in the making of cinder units is not plastic, it is molded under high pressure. The process is therefore entirely different from that of placing concrete on the job, and the question of consistency cannot be considered in the same light.

As a matter of fact, factory-made 1:7 cinder concrete contains almost as much water per sack of cement as the 1:2:5 sand-cinder concrete discussed by Mr. Strehan. This water does not "drain off rapidly," as Mr. Strehan claims—it is held for a long time by the cellular concrete and is available for hydration of the cement to the same degree as in a sand-cinder concrete.

It is unjust to say that the matter of mixing water is generally neglected in cinder unit plants. The mixer man quickly learns to judge his mix with a fair degree of accuracy, and the figures of 4 to 5 lbs. of water per cubic foot of aggregate, suggested by Mr. Strehan, do not in any way represent mixtures actually used. The figures given by the writer, of approximately 1.5 gallons (12 lbs.) per cubic foot, are typical.

Mr. Strehan assumes that this "dry mixed" cinder concrete causes trouble in the wall. He says that "the high expansional movement of cinder concrete normally associated with its early life is very likely to be prolonged to the masonry in the wall because of the slow hydration of an all-cinder concrete mixture." The fact remains, however, that volume change of cinder concrete masonry, if occurring at all, is a contractional movement similar to that of other concretes, accompanying further hydration of the cement and the drying of the masonry. As shown by the tests quoted in the report, such shrinkage movement is avoided when the concrete units are properly aged and dry.

The writer will be interested in knowing the facts that justify the statement of "lack of durability or permanence in the structure as well as the corrosion of embedded steel occasionally demonstrated by the rusting of nails driven into the masonry." It is contrary to the ten-years experience of the writer in the cinder unit industry. The product has enough history back of it to show its permanence—and the almost universal nailing of trim and grounds to cinder concrete masonry affords ample opportunity to observe the conditions of the nails. That nails driven into the outside of walls may rust, is natural when they are exposed to rain and not sufficiently protected by the surrounding concrete.

To Mr. Strehan, sand is a necessary constituent. That it is frequently desirable in order to produce workability in job-placed concrete is true—that it does not of necessity improve the concrete is shown in the paper. And matters are quite different with cinder concrete building units, molded under heavy pressure.

Mr. Strehan does not think much of the "cinder fines." Nevertheless, his own tests (quoted in the report) show a decrease in strength of sand-cinder concrete when the fines were screened out. Examination of the interior of cinder concrete (molded under pressure) shows a homogeneous concrete—cellular, but nothing like the "mass of coarse unattached particles" pictured by Mr. Strehan.

The supplement by Mr. Peck contains some interesting information regarding the effect of grading. Apparently, the fine-coarse ratios reported have reference to a straight cinder aggregate, indicating what may be accomplished without the addition

of sand. That the latter becomes important where the cinders are lacking in fines, appears obvious. But the self-contained cinder aggregate, reported to split 50–50 on ¼ in., is stated to produce a "true plastic mix."

Mr. Strehan's long experience with sand-cinder concrete in New York adds valuable data on the nature of the New York material. That this "sand-cinder concrete" does not behave exactly like the "cinder concrete" used in machine-made units, is one reason why the writer suggested the two names to differentiate the different materials.

To sum up: It appears to the writer that Mr. Strehan fails to appreciate the fact that factory-made cinder concrete is different from job-made sand-cinder concrete, not merely in having a straight cinder aggregate (graded from coarse to fine) and in having a different consistency, but also in that it is molded under pressure and cured under conditions where the aging can be controlled. Actual performance and accelerated laboratory tests have shown that such factory-made cinder concrete is permanent and offers full protection for any steel properly embedded therein.

The writer has little to add to the interesting discussion by Mr. Praeger. While the matter of design of reinforced cinder concrete was considered to be outside the scope of the report, it is nevertheless an important one as pointed out in this discussion, and it is to be hoped that further work will be done to develop more accurate and uniform specifications.

Readers are referred to the JOURNAL *for December 1931 (Vol. 28), for further disussion. Such discussion should reach the Secretary by Nov. 1.*

A Discussion of a Paper by Raymond E. Davis and Harmer E. Davis:

"Flow of Concrete under the Action of Sustained Loads"*

BY G. A. MANEY† AND M. B. GAMET‡

The well established fact that plastic flow is increased 200 to 300 per cent or more by the drying out of a specimen, which, is identical in all details of mix and strength, leads us to look to shrinkage for an explanation. A paper is being prepared describing the results of a series of experiments at Northwestern University which gives an explanation not only of this phenomenon, but of the decrease in the modulus of elasticity of dry specimens which are identical in strength and mix with specimens tested wet.

A series of pairs of 8 x 32-in. cylinders, one hollow with a ¾-in. shell and the other solid were investigated for shrinkage. 20 in. longitudinal gauge lines were read on the surface of both specimens, and a special 32-in. instrument was designed to read between end points, as shown in Figs. (4) and (5) and was used to get the variation of shrinkage at the several points indicated in the interior of the specimen.

Our best information at present would indicate that the surface shrinkage of the solid specimen will eventually approach closely that of the hollow one, but a tremendous lag is seen in Fig. 3 at all intermediate ages. As this paper is in the nature of a progress report, only 20-day values are available.

Fig. 6 shows the comparative deformations of solid and hollow specimens at age 20 days, and Fig. 7 indicates approximately the

*A. C. I. Journal, March, 1931; A. C. I. *Proceedings*, Vol. 27, p. 837. Submitted as a part of the work of Committee 109, Summary of Plastic Flow, Raymond E. Davis, author-chairman.
†Professor of Structural Engineering, Northwestern University, Evanston, Ill.
‡Instructor in Civil Engineering, Northwestern University, Evanston, Ill.

stress distribution which must exist under *no load*. The surface tension f_t is measured by the difference between the unrestrained surface shrinkage e_c, as obtained from the shell, and e'_c which is a restrained surface deformation, greatly reduced below e_c, because of the very slow shrinkage of the interior of the solid specimen. Figs. 8 and 9 show the difference between probable and commonly assumed stress distribution.

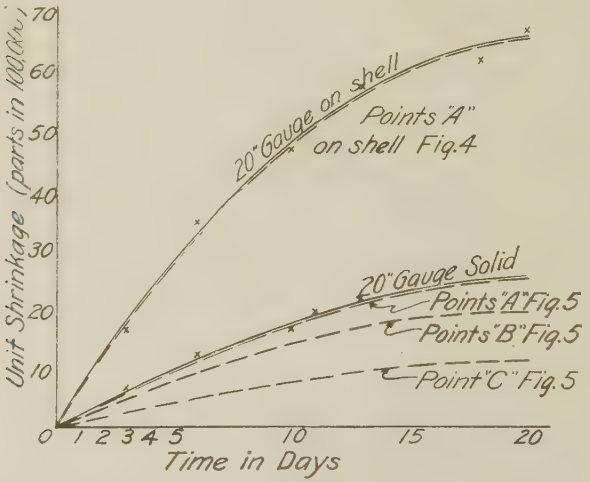

FIG. 3—CURVES SHOWING RELATION BETWEEN TIME AND SHRINKAGE IN SOLID AND HOLLOW 8 IN. X 32 IN. CYLINDERS FOR 1:1:1 MIX (BY WEIGHT) WITH APPROXIMATE 8 IN. SLUMP

If we assume, as is closely true for wet specimens which eliminate the shrinkage problem, that flow is proportional to unit stress, this distribution of stress explains all of the high flow values obtained in the dry specimens discussed in this report. Under low loads the actual stress may be 3 to 6 times greater than the average stress, and only (in the case of the specimens discussed here) at a deformation difference of .00040 which represents 1600 lb. per sq. in. at age 20 days (using $E_c = 4{,}000{,}000$) would this ratio come down even to a 2 to 1 ratio. It is doubtful in a solid specimen of appreciable size whether the interior shrinkage ever reaches the surface value.

FIG. 5—PLAN OF END OF SOLID SPECIMEN SHOWING LOCATION OF PLUGS FOR READINGS WITH SPECIAL MICROMETER INSTRUMENTS

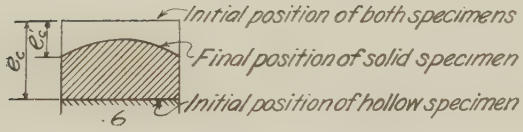

FIG. 6—COMPARATIVE UNIT DEFORMATIONS OF SHRINKAGE ON HOLLOW AND SOLID SPECIMENS

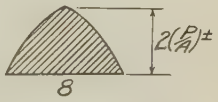
FIG. 7—APPROXIMATE STRESS DISTRIBUTION UNDER NO LOAD

FIG. 8—STRESS DISTRIBUTION UNDER LOAD AT TIME WHEN OUTSIDE TENSION IS JUST ELIMINATED



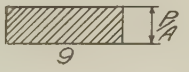


FIG. 9—COMMONLY ASSUMED UNIFORM STRESS DISTRIBUTION

We also wish to submit Figs. 1a to 1d and Fig. 2 (See page 1299), which are practically self explanatory, and which bring out forcibly the fact that a companion specimen with the same steel as a loaded specimen has no bearing on the problem of how the total time increment is divided between shrinkage and plastic flow. In general, when the proper control specimen (which is always plain concrete for a column with vertical steel) is used, shrinkage will account for all of the stress due to time, if no load is applied directly to the steel, but gets to it only through bond as is universally the case in practice. In the specimens of the paper discussed, since load is transmitted directly to the ends of the steel bars, any plastic flow deformations in the concrete cannot take place without carrying the steel along. In practice this is not the case, and so far the specimens tested in the Northwestern University laboratory indicate that flow can take place in concrete around the bars without in any way affecting their stress.

BY J. R. SHANK*

The writers of this paper are to be commended for the easily readable presentation of this work. The writer of this discussion, who had no part in the work of this paper, has some data which he has obtained under different conditions of materials and procedure which he would like to present. Four curve sheets and a sketch are presented bearing on the effect of mineral character of aggregates, on the effect of the amount of load, and on the creep or flow of reinforcing bars in compression splices. These are the results of bachelors' theses carried out at the Ohio State University under the close supervision of the writer.

Fig. 1 shows the results of tests of concretes made up of aggregates of two widely different characters, crushed limestone and silica gravel. The same material was used for both coarse and fine in all specimens. These specimens were made up and tested in a manner similar to that described by the writer in a discussion A. C. I. *Proceedings*, 1928, of a paper by Raymond E. Davis on this same subject. The limestone used was a local product known as Columbus limestone. It is a rather hard fossil-bearing limestone used for concrete and to some extent as a building stone. A notable example of its use as a concrete aggregate is in the Ohio Stadium and as a building stone in the State Capitol at Columbus.

*Professor, Dept. of Civil Engineering, Ohio State University. Critic member Committee 109.

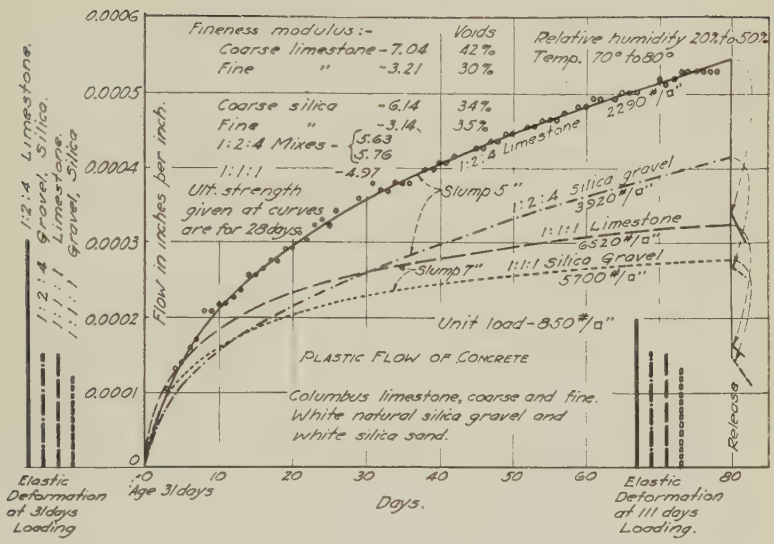

FIG. 1—CURVES SHOWING PLASTIC FLOW OF CONCRETE

It is of a yellowish white color and it breaks in crushing to particles of a generally regular polyhedral shape. There is some tendency to break into somewhat elongated pieces, but none into flat plate-like shapes. The fine limestone aggregate had the fine flour washed out. In this shape it is a commercial product sold for concrete construction. The silica material was obtained from a gravel bank near Akron, Ohio. It has nearly white translucent smooth particles of quartz both coarse and fine.

The investigation was made on two mixes, one a rich mix rather wet and the other a more common mix. The conditions of fineness modulus, consistency and curing conditions were the same in the specimens of each mix. Considering the richer mix, it will be noticed that the amount of flow at 80 days is very nearly inversely proportional to the strengths obtained. This is contrary to the general expectations. The stronger concretes usually flow less. The instantaneous deformations and recoveries appear to be very nearly the same though one occurred at 31 days and the other at 111 days. The leaner mixes show limestone with the greater flow and the lower strength, and the difference is more marked than for the rich mixes.

These specimens were kept during the loading time in ordinary room temperatures and humidities after having been cured in damp sand at about 75 deg. F. room temperature for 31 days. The time of the year was winter and spring. The room was steam heated and the temperature ranged between 70 and 80 deg. F. The relative humidity varied from 20 to 50 per cent which is usual for the interiors of heated buildings for this time of the year where no effort at humidifying the air is made. The changes due to temperature and humidity variations are eliminated from these curves by correcting each reading by a deformation observed on a similar specimen from the same batch cured and stored at all times with the specimen in the test, and treated in all cases the same excepting that it was not under external loading. All four loaded specimens with their respective idlers were kept in the same room. These curves are therefore comparable with each other and can be compared with other curves for specimens under about the same conditions of temperature and humidity. They certainly represent the condition of concretes inside of buildings.

In the cases of both mixes whether stronger or weaker the limestone concrete showed more flow than the silica gravel concrete. This is contrary to the results shown on Fig. 6 of the report. The non-agreement of the results from these two sources indicates that there is considerably more to be learned about the effect of the mineral character of aggregates on flow. As a part of this work an attempt was made to look into the plastic flow properties of aggregate materials themselves. Specimens of three common building stones were secured and put through the same tests as were the concretes. Fig. 2 shows the results. The Columbus limestone came from the same quarry from which the limestone aggregate was taken. The Indiana limestone was furnished by the Indiana Limestone Co., Bedford, Indiana, from quarries of the well known oölitic Bedford or Indiana limestone. The Amherst Sandstone was furnished by the Ohio Cut Stone Co., Cleveland, Ohio. This stone is a fine grained light buff colored silica-bound sandstone. It has a high rating as a building stone. Two specimens were tested, one along the grain and the other across the grain. The specimens were all loaded and unloaded once or twice

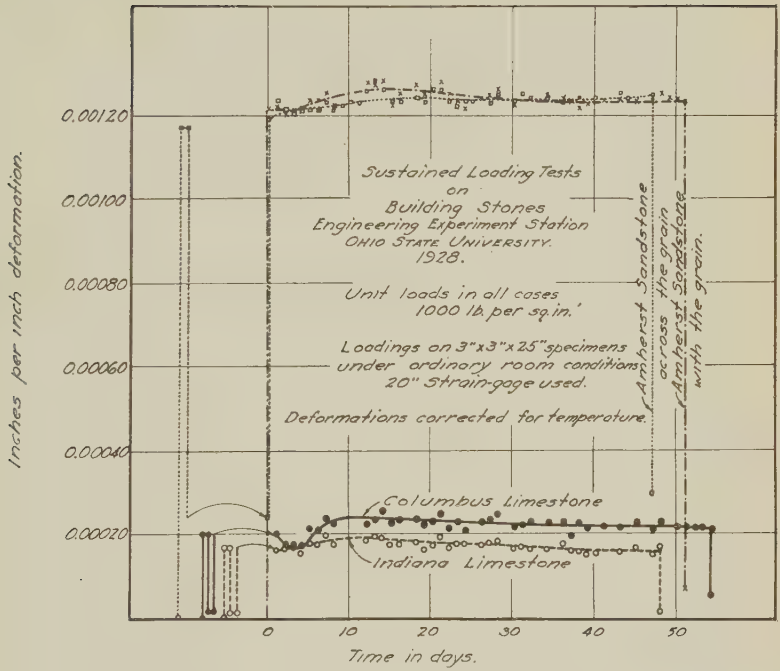

FIG. 2—SUSTAINED LOADING TESTS ON BUILDING STONES

before they were given the sustained loading. Fig. 2 shows this to the left of the sustained loading graphs.

It will be noticed immediately that there is no appreciable plastic flow in these building stones. The Amherst stones seemed to show some in the first few days which, however, was hardly apparent at the end of the 50 days. It is interesting to note the large differences in the elastic properties of these stones and that Fig. 6 of the report shows sandstone as an aggregate to have the greatest flow while Fig. 2 of the discussion shows the Amherst sandstone to have the low modulus of elasticity. It is regretted that Fig. 1 shows no concrete made of Amherst sandstone as an aggregate. These few tests indicate that the plastic flow in concrete is not due to any large flow in the aggregate particles themselves. This leaves the shapes of the particles and the surface conditions to be considered. The amount of surface and the

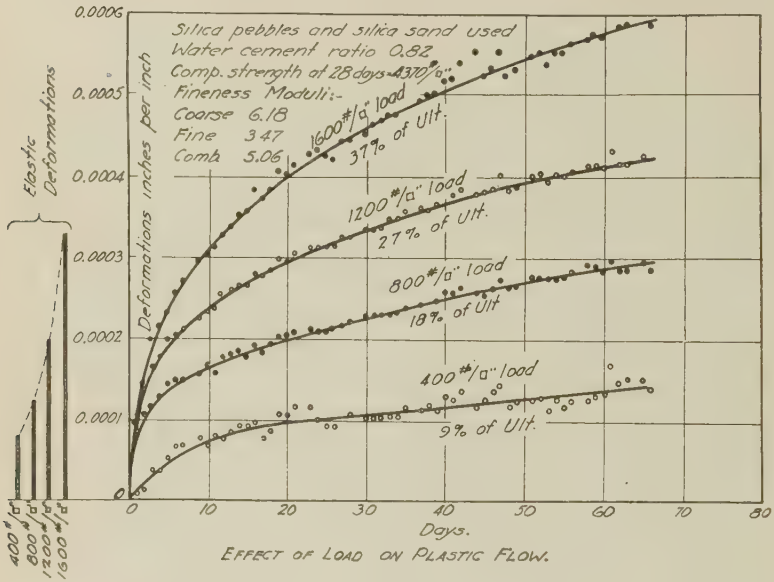

FIG. 3—EFFECT OF LOAD ON PLASTIC FLOW

character of the bonding of the cement to the surface of the aggregate particles are factors to be considered. It appears that other classifications than those given in this report will have to be made before this matter can be finally presented.

Fig. 3 shows additional data on the effect of stress upon air stored specimens loaded at 28 days. This corresponds with Fig. 10 of the report and shows similar results. The discussion shows a stronger concrete in which higher unit stresses were used. The loading period was very much shorter. Here again the conditions were those of a building interior in the winter time. The results from these two sources are in close agreement. Technical Paper No. 12 on building research of the Department of Scientific and Industrial Research of Great Britain by W. H. Glanville, Fig. 10a is also in agreement. Similar results from these three independent sources might warrant the conclusion that in general the flow is proportional to the stress within ordinary working load limits. What occurs for stresses nearer the ultimate load remains yet to be investigated.

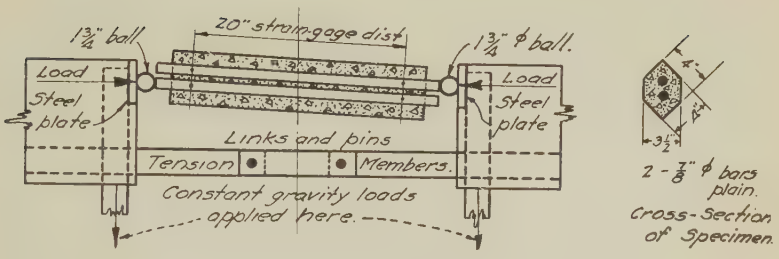

FIG. 4—SKETCH SHOWING SPECIMEN AND METHOD OF LOADING

Figs. 4 and 5 illustrate the results of an attempt to find out whether there is an appreciable bond flow or shear flow in the splices of bars in compression members such as building columns. Fig. 4 shows part of the apparatus used for the flow tests described in this discussion carrying a specimen for this particular investigation. As the load is a gravity load there can be little or no variation in the load. Specimens were made with ⅞-in. plain round bars close, ½ in. clear between, 1 in. clear between and 1½ in. clear between. They were made in pairs and cured in damp sand for 28 days at which time one of each was set up in one of the loading devices. A load of 12,500 lb. was applied to each. The specimen whose bars were 1½-in. clear between failed by diagonal tension. Another pair of specimens of similar concrete was made up, cured and loaded at 28 days with half the load. Strain-gage readings 20-in. long were taken on two sides of the specimens, two on each bar and four from bar to bar. From these data the horizontal movements of the points at one end on one bar was computed with respect to the points at the same end on the other bar. The results for the two ends of the specimen averaged gave the horizontal movement of one bar with respect to the other. These results are shown on Fig. 5 together with the flow of plain concrete of the same batch and of the same cross-section. The unit stress on this plain concrete was 915 lb. per sq. in. For the specimen having bars 1½-in. apart the deformation data were doubled before plotting so as to make the results comparable, assuming that the flow was proportional to the load. To

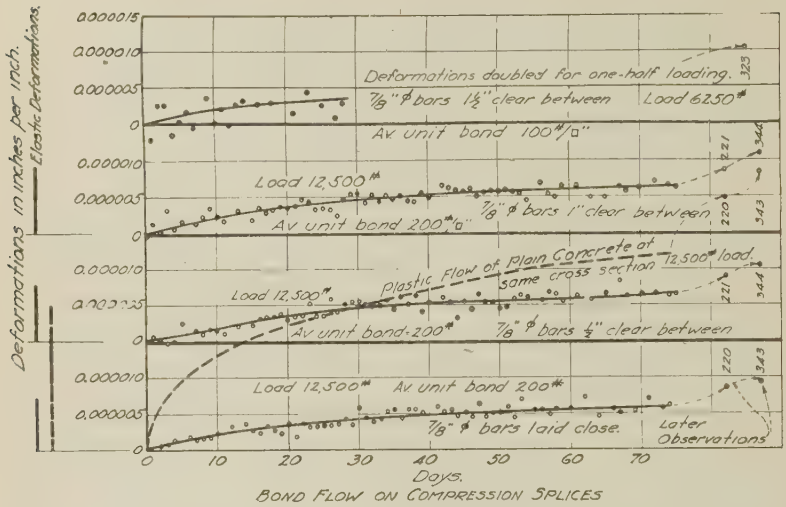

FIG. 5—BOND FLOW ON COMPRESSION SPLICES. MIX 1:2.24:2.52 SAND AND GRAVEL W/C = 0.80, SLUMP 3 IN., COMPRESSIVE STRENGTH 4200 LB. PER SQ. IN.

the data of the original thesis were added deformations at later dates which are shown as separate points to the right of Fig. 5.

It is clear that there is a movement of the bars with respect to each other and that this movement must be in the region close to the bars since the distance between the bars has very little effect. We might say that we have "bond flow," but little or no "shear flow" even though the diagonal tension arising from the shear was near the ultimate as was evidenced by the failure of the specimen having bars 1½-in. apart. At the latest date shown the movement for all specimens did not vary from 0.00001 in. per in. by more than 8 per cent. The doubled value for the specimen having bars far apart was within this limit at 297 days. At 74 days loadings the plain concrete flow was 4.3 times the average bond flow, at 220 days, 4.1 times, and at 343 days 3.8 times. This situation must make considerable difference in the distribution of stresses in tall building columns where bar splices occur at every story height. The average unit stress in the steel is, therefore, not as much as the total shortening of the column would indicate. There would also be variations in the unit stresses along the

lengths of individual bars, the greatest being at the middle of the length and usually at the mid-story heights. The carry into the column of bending from floor beam deflections would be greater into the column below the floor than above, since splices are usually made just above the floor. The point of inflections would then tend to be below the mid-story height or where full elastic action on the column would indicate.

BY LARS JORGENSEN*

The paper "Flow of Concrete under Sustained Stress" contains information of a very important nature.

It is still customary when calculating stresses in concrete structures to use the E corresponding to the instantaneous deformation, where—as is shown in this paper, the flow for sustained load greatly influences the working E.

These tests, the writer understands, were started with the object of finding the elastic property of the concrete, which went into the Stevenson Creek dam.

On dam construction an additional factor enters into the problem, namely the watersoaking effect. The results of these tests show quite conclusively that the E for wet concrete is much higher than the E for dry concrete. This is especially of considerable importance in the calculation of dam structures, where part of the dam body is wet and part of it dry, which is always the case when the structure is loaded.

For dam design another property peculiar to concrete is of great importance and that is the watersoaking effect or rather its distribution throughout the section. If the authors would extend their investigation to also include this item, they would have the subject covered rather completely.

The distribution of the watersoaking effect is perhaps quite a difficult subject to investigate, but its importance will justify any earnest attempt to surmount a great deal of difficulty.

For ordinary building design the result of the authors tests points towards the necessity of making two sets of stress calculations, one set using the ordinary or instantaneous E and one set using what the authors call sustained modulus of resistance for concrete under load (for say at least 2 years).

*Consulting Hydro-Electric Engineer, San Francisco.

For dam design the instantaneous E would hardly ever be considered, since the load on such structures comes on gradually and goes off gradually. Take a straight gravity dam for instance,the reservoir being first empty gradually fills up; the stress along the upstream face being first a maximum and later diminishes to nearly zero, while the stress along the down stream face gradually increases from a moderate amount to the maximum allowable compression with reservoir full.

Had the reservoir been empty long enough to produce flow action in the concrete along the upstream face, this face would probably have deflected in an upstream direction. With reservoir full the E for sustained modulus of resistance would have to be used, when calculating the deflection in a downstream direction especially after the reservoir has been full for some time.

The calculated deflection using the sustained modulus of resistance instead of the instantaneous E would be nearly double. To this deflection would have to be added a certain amount due to the watersoaking effect in the cantilever. The upstream face of the dam is 100 per cent wet and the downstream face is dry or nearly so on a well built dam. The upstream face therefore expands vertically relative to the downstream face, this occurrence is compensated for by additional deflection in a downstream direction of the cantilever and without setting up any additional stresses.

The stress distribution along any horizontal joint of a straight gravity dam is not necessarily changed on account of using the sustained modulus of resistance instead of the instantaneous E. This distribution will most likely be in accordance with the theory given by B. F. Jakobsen in a paper before the Am. Soc. Civil Engineers (*Proceedings* Am. Soc. Civil Engineers, September, 1930).

The much larger deflection due to the use of the sustained modulus of resistance instead of the instantaneous modulus of elasticity and the addition to this deflection due to the watersoaking effect is of no special importance for a straight gravity dam, but it is of great importance on a curved dam, because on a curved dam, there is a possibility, that the load may be carried on two systems, arch and gravity (inversely proportional to their deflections).

When calculating the deflection of an arch dam in a down stream direction, the working modulus of elasticity will be considerably higher than the sustained modulus of resistance for dry concrete, since the upstream face is wet when under stress. The portion of the system (cantilever) which might carry load by gravity action is dry where it has its maximum stresses. The wet upstream face expands along the horizontal arch and this is equivalent to an increase in E, a decrease in arch deflection and a decrease or elimination of tensile stress at the abutments.

The wet upstream face also expands vertically, this affects the cantilever as it produces a deflection in a downstream direction without setting up any stresses and therefore without carrying any load. Should the vertical cross section of the dam be such that the deflection of the cantilever due to watersoaking effect in the cantilever is equivalent to the arch deflection, assuming the arch to carry all the load, then the cantilever does not carry any load at all since the water soaking effect in the cantilever made it deflect without setting up any stresses.

If the cantilever deflection due to the watersoaking effect is less than the deflection due to full load on the arch, then of course the cantilever will take some load, since the deflection of the two systems must be the same.

Not so very much is known about the distribution of the watersoaking effect in a body of concrete wet on one face and dry on the opposite face and it is therefore not warranted to assume that the arch receives a definite support from the vertical cantilever.

As already stated, if the authors could be induced to carry on experiments on the distribution of such watersoaking effect in concrete, some valuable information undoubtedly would be forthcoming on this rather dark subject.

CONVENTION DISCUSSION

CLOYD M. CHAPMAN—I was asked the other day whether any tests were made to determine if the sustained load due to the car springs used in the testing apparatus was constant.

RAYMOND E. DAVIS—The springs have been periodically tested to determine whether or not there was any dropping off in load and so far as we have been able to determine within the precision of our measuring apparatus, certainly within 2 or 3 per cent, I

think probably closer than that, it would be within the precision of the measuring apparatus. Therefore we may say that no appreciable dropping off of load has taken place within the limit of the experiment. Any dropping off that has taken place is negligible.

Readers are referred to the JOURNAL *for Dec. 1931 (Vol. 28), for further discussion which may develop. Such discussion should reach the Secretary by Nov. 1, 1931.*

Discussion of Second Progress Report of Committee 105

"Reinforced Concrete Column Investigation"*

BY G. A. MANEY†

The undeniable evidence of this remarkable and much needed investigation is to throw into the discard the time honored assumption of "nf_c" as representing the *total* unit stress in compressive steel. Also the additional stress due to "time" which we may most easily call $e'E_s$, where e' represents the unit deformation due to time yield, becomes a correction which not only doubles but often trebles our unit stress due to instantaneous loading.

Having been in possession of this almost universally unrecognized fact for a number of years and having published several articles as a result of experimental investigation of the compressive steel of beams in our laboratory at Northwestern University, I have been impressed with the seeming indifference of the profession to these facts. For years we have been using a formula for reinforced concrete column design which has introduced this tendency to high compressive steel stresses and have calmly ignored this same phenomenon in the calculation of compressive beam steel. It should be noted however that not even a reasonably small percentage of those using the A. C. I. column formula have understood the conception. Many of those who did realize they were using a code which was based on high design units in compressive steel, were not willing to admit that even stresses approaching the elastic limit in compressive steel under design loads should hide the fact that at ultimate load all the three elements (vertical steel, spiral steel and concrete of core) will be developing as a minimum their full capacities at elastic limit stresses.

*A. C. I. Journal, Feb. and March, 1931; *Proceedings*, Vol. 27, p. 685.

†Professor Structural Engineering, Northwestern University, Evanston, Ill.

The large scale and wide scope of this investigation which goes for the first time into the much neglected field of time loadings must eliminate any doubt as to the astounding divergence between what the average designer of reinforced concrete structures thinks he is getting and what actually occurs. Code changes in *all* compressive steel stresses are inevitable. I see in the recognition of these important findings many possibilities for reduction of size and dead weight where (as is often the case) this is desirable. We begin to realize as we get into these results that from 50 to 90 per cent and (in many cases) all of the column load is carried by vertical steel alone. This leads us to think of a new type of column with greater percentages of vertical steel and much *higher elastic limits* in vertical steel.

Much question of the relative contributions of shrinkage and plastic flow to this tremendous time increase will arise. In our investigations of compressive beam steel under continued load at Northwestern University we have been able to conclude (see *Engineering and Contracting*, June 10th, 1930) that shrinkage has a controlling effect on time stresses in compressive steel and that plastic flow, although an important quantity in plain concrete (as has been shown by Davis and others) is negligible in its effect on increased steel stresses.

The control or companion specimen used to determine shrinkage under no load is the all important detail in separating the two effects.

An examination of Figs. 1*a* to 1*d* brings out clearly the fact that a control specimen such as shown in Fig. 1*b*, of plain concrete and with unrestrained shrinkage unit change of e_{sh} is the only kind which will give any information on the question of shrinkage contribution to the true increment of compressive steel stress. A companion specimen exactly the same as the one under load and having the same compressive steel (Fig. 1*a*) does not tell more than merely how much compressive stress shrinkage *alone*, without the help of load, can throw into steel. The resulting unit change e, has no bearing whatever on the stresses resulting from the column under a deformation e_3 which exceeds e_{sh}.

Fig. 1*d* shows the total stress in compressive steel under load and shrinkage only as $(nf_c + e_{sh}E_s)$, where e_{sh} can only be the unit shrinkage of the plain concrete companion specimen.

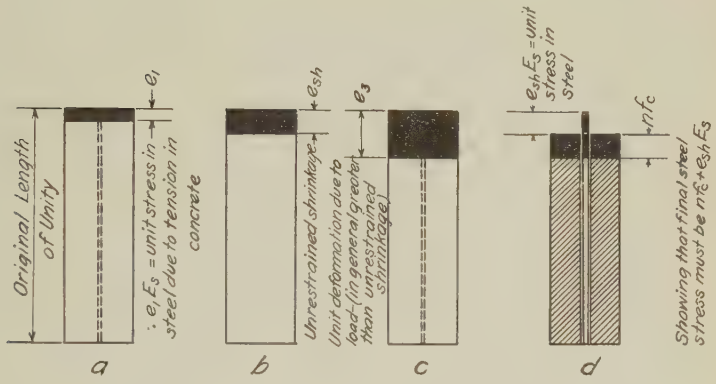

FIG. 1.

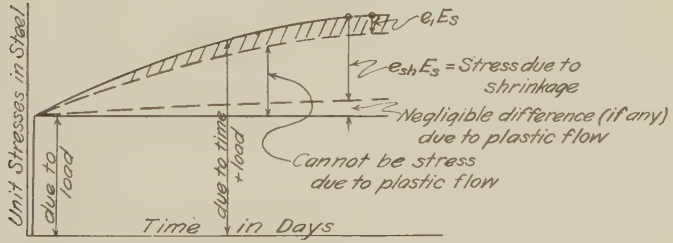

FIG. 2—CURVES ILLUSTRATING NEED OF PLAIN CONCRETE SPECIMENS FOR SHRINKAGE CONTROL

It is a notable fact that time increases in measured compressive beam steel check remarkably in an extreme range of cases with the shrinkage of plain unloaded beams of same section with no steel.

It is doubtful if plain concrete shrinkage will fail to account for all except a negligible part of total time increase in the columns of this series. In Fig. 2 is seen the difference in plastic flow effects which would result from a use of the two different kinds of control specimens.

BY WARREN RAEDER* AND HERBERT J. GILKEY†

One of the main purposes of the extensive and admirable column investigation being carried on by Committee 105 is a study of the maximum steel stresses reached in reinforced

*Assistant Professor of Civil Engineering, University of Colorado.
†Professor of Civil Engineering, University of Colorado.

columns due to live load, shrinkage, and flow, and the influence such stresses may have upon the effective strength of the column. Various investigators over the past 20 years, notably McMillan and Lagaard, have reported stresses in the steel approximating yield point values. The question naturally arises: if the reinforcing bars are stressed to the yield point, in what condition is the column to take its load?

The authors of this discussion, in an attempt to study this problem qualitatively, recently cast some compression specimens with the reinforcing bars protruding at the ends so that under test there would be no question about the bars being stressed to the yield point. This stress the bars received before the concrete ends of the specimens came into contact with the testing machine.

A description of the specimens together with the ultimate loads they took is given in Table 1. Specimens 1a to 6a inclusive were of 1:2½:4 concrete with a water-cement ratio of 1.0. The remainder of the specimens were of 1:2:2½ concrete with a water-cement ratio of 1.0 and a coarse aggregate of ⅜ in. to ½ in. pea gravel. The ½ in. square bars used extended approximately ⅛ in. at each end and the ¼ in. round bars .05 in. It will be noted that some of the bars were greased and that in specimen No. 7 the bars were greased and were flush with the ends. All bars had milled ends.

The purpose of the experiment, which was in the nature of reconnaissance only, was to study the behavior of the specimens when the reinforcing bars were definitely stressed to the yield point in order to learn whether the concrete would crack and, if so, how badly; in general, to draw conclusions as to the ability of the reinforced concrete column to take axial load with the steel under a stress at which it would definitely flow parallel to the load, or buckle if not laterally restrained. The specimens were watched particularly at three stages of the testing: (1) at the yield point of the steel; (2) when the specimen as a whole reached its yield point—that is, when it deformed rapidly without taking appreciably greater load; (3) after failure. Continuous stress-strain measurements were taken semi-autographically on all specimens. The specimens were cured under water and tested at 28 days. Results may be summarized as follows:

(1) Specimens without spiral reinforcement cracked badly when the steel reached the yield point. The 3-in.-diameter specimens, with a single ½ in. square bar at the center, failed at this stress while the protruding bars were far from being flush with the concrete; that is, the steel took very little deformation at the yield point before failure by splitting occurred. The similar 6-in. diameter specimen showed cracks at the yield point of the steel (at a total load of 12,000 lb.) but took an additional load of 46,700 lb. (58,700 total) before failure occurred. The bars were about flush at this load. The corresponding specimen, No. 6, with spiral steel, took 162,000 lb. ultimate in the case of the greased bar and 149,000 lb. in the case of the bar not greased (specimen No. 5).

(2) All specimens which had spiral reinforcement were in excellent condition when the stress in the steel reached the yield point. Under further loading, which caused the bars to gradually sink into the concrete until they were flush, some local cracks and spalling developed but in all cases the core was in very good condition.

(3) The specimens with greased bars took, with some exceptions, a slightly higher load than those with bars not greased. Specimen No. 7 with bars greased and also flush showed no cracks at failure at all and was in the best physical condition of all 6 by 12 in. specimens.

The behavior of the specimens with greased bars indicates that perfect bond between concrete and longitudinal steel, which has been a time-honored assumption for purposes of design, is not essential for developing the carrying power of columns under axial load provided some other adequate means is supplied for transferring load to the steel. In the columns of these tests the metal end bearing blocks accomplished the positive transfer of load to the projecting steel bars in the same manner as would be accomplished by properly designed butt joints or flush end plates. It should be understood that the greased bars of the tests were employed only as a device for bringing out a different aspect of fundamental column action. No implication is being made that such construction should be followed in column design.

*Bars flush with ends.
**Average of three specimens.
***Average of two specimens.

Whether it possesses any merit for purposes of construction is beyond the scope of this discussion.

As to the behavior of columns whose longitudinal bars become stressed to the yield point due to shrinkage and flow as well as normal design loads, it is to be concluded from these tests that columns with adequate spiral steel should be structurally safe.

The importance of proper spiral reinforcement can scarcely be over-emphasized. All reinforced column research to date seems to point to this conclusion. In this instance, too, it is evident that the spiral steel furnished the lateral support tending to keep the concrete from splitting and to restrict the splitting when it did start. By confining the concrete surrounding the longitudinal steel it enables the latter to continue to take its maximum stress even though the yield point is reached and it

allows the concrete to approach and even exceed its ultimate strength as indicated by similar specimens of plain concrete.

In conclusion it may be stated that the specimens described above were punished more severely than specimens in which the bars are flush with the surface of the concrete, due to the pressing of the steel into the concrete and the consequent greater force exerted upon the column tending to split it. It is encouraging, therefore, that the results point to the same conclusion as that indicated by previous observations and apparently forecast by the preliminary report of Committee 105, namely, that one need feel no undue concern regarding the structural safety of the reinforced concrete column as a result of the longitudinal steel being rtressed to the yield point provided the column is adequately reinforced with spiral steel. What constitutes adequate spiral reinforcement continues to be one of the major questions before Committee 105.

Readers are referred to the JOURNAL *for Dec. 1931 (Vol. 28), for further discussion which may develop. Such discussion should reach the secretary by Nov. 1, 1931.*

Discussion of Report of Committee 308

"Basis of Design for Hurricane Exposure"*

Discussion of the report of this committee, published in this Journal March 1931, Vol. 27, p. 903, was scheduled for this month. It has been deferred to September 1931, Vol. 28. —Editor

Discussion of Paper by Benjamin Wilk:

"A Comparison of Continuous with Batch Mixers in Plant Operation*"

CONVENTION DISCUSSION

H. B. Emerson: Did you have any way of measuring accurately the water used in the continuous mixer to a given amount of cement and aggregate as in the batch mixer?

Mr. Wilk: No, but we can tell from the face of the block whether or not it has the proper amount of water in it. Variations will show up noticeably—the water web mark is about as good an indication as we could have. If there is too much water the block will slump; if not enough the water web mark will not be there and the possible variation is not a great deal; John Lowell just advises me that the water variation, as so observed, is less than can be conveniently measured.

A. G. Conrow—Did you make any comparison of the number of turns in the use of the continuous mixer and in the batch mixer—the turns of the material.

Mr. Wilk—That question brings up one's ideas of a batch mixer and of a continuous mixer. The batch mixer is called upon to turn together all the cement and all the aggregate which are brought together at one loading. But in the continuous mixer I am talking about, very small portions of the aggregates and of the cement are thrown together at one time so that if for example, four cubic feet of material is divided by thirty-four of the blades, a very small proportion of material strikes a blade at a time, and it is that combination of small amounts of cement and small amounts of aggregate which, to my mind, causes the thorough-

*A. C. I. Journal, Feb. 1931; *Proceedings*, Vol. 27, p. 655. Presented by Mr. Wilk and discussed at 27th Annual Convention, Milwaukee, Feb. 24-26, 1931.

ness of the mixing and which it looks to me is very difficult to get in a batch mixer. If you are going to put in eight cubic feet of aggregate and on top of that throw one cubic foot of cement, it is going to take quite a while to mix it as thoroughly as in a continuous mixer where small portions of the material are thrown together at one time in the mixer trough.

Discussion of Paper by H. F. Faulkner and R. R. Hubbard:

"Design and Control of Concrete for Diablo Dam*

DISCUSSION BY F. R. MCMILLAN

It is very gratifying to have in the *Proceedings* of the American Concrete Institute this description of the concrete and of the unique methods of placing used in the Diablo dam. In both of these features this project provides significant departures from the practice which has become almost standard for large dam construction. The speaker had the good fortune to visit this structure in company with the authors and Mr. Carver, and can testify to the success which attended these methods.

The use of large sized aggregate for structures of this size has

*A. C. I. Journal, February 1931; *Proceedings*, Vol. 27, p. 529. In the absence of the author, the paper was presented at the 27th annual convention, Milwaukee, Feb. 24-26, 1931, by F. R. McMillan, who called attention to the outstanding features of the work and presented discussion as here published.

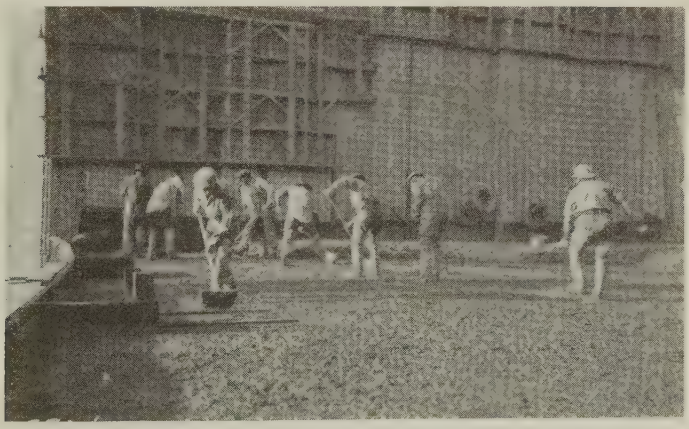

Fig. 1—Brooming surface with mortar just before placing a layer of concrete

FIG. 2—COMPLETED DAM, DIABLO CANYON

become so nearly universal in recent years that the limitation of this aggregate to a maximum size of 4 in. will, no doubt, attract considerable attention. The authors have set forth quite clearly the reasons for this limitation. While advocates of the use of "cobbles" up to 8 or 10 in. can show successful results to offset some of the claims, instances can be cited of results not as satisfactory as at Diablo Dam. The mixtures with 4-in. maximum size showed up particularly well under the method of placing used which, as pointed out before, was also an innovation in constructions of this kind.

Figs. 4 and 5 of the paper show the belt conveyors suspended from the tower and boom. Both towers in Fig. 4 are seen to be rigged in this manner. Fig. 6 shows the "elephant trunk" through which the concrete was deposited. Something of the character of the mixture can be seen from this view. The absence of a great range in sizes, together with the method of placing, practically eliminated all undesirable segregation and required a minimum of handling and puddling.

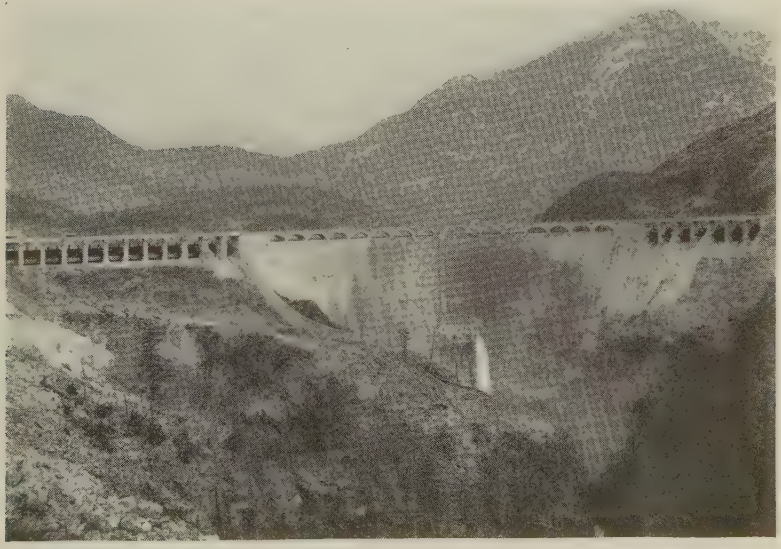

FIG. 3—COMPLETED DAM. DARKENED PORTION OF FACE IS WET WITH SPRAY FROM STREAMS PASSING THROUGH NEEDLE VALVES

Three views are here added to those presented by the authors with the paper.

Fig. 1 shows the brooming of the surface with mortar just before placing a layer of concrete, as described by the authors. Placing the concrete in thin layers, which can be seen in this picture, insured a thorough puddling and at the same time reduced tendency to the formation of laitance.

The success of the method, of course, can be judged only by the final product. Figs. 2 and 3 show the completed dam with the reservoir practically full. As brought out in the paper there is some leakage on some of the horizontal joints. This leakage however, is restricted to a very small number (less than 1 in 20, it appears from the pictures) and to very small amounts.

This tightness is extremely favorable in comparison with some of the better constructed dams of comparable dimensions in which 8 and 10-in. aggregate was used. The fact that so large a proportion of the joints is perfectly tight is evidence that the mixtures and methods were entirely adequate. Such defects as are noted only emphasize the need for constant attention to all the details of preparation of surfaces and placing the concrete to obtain perfect results.

Discussion of Paper by J. L. Mensch:

"Composite Columns"*

BY FRITZ EMPERGER†

In the infancy of the reinforced concrete era two different view-points opposed each other. One of them leaned towards steel construction and considered concrete as a filler between rigid reinforcements. The other would improve the concrete by flexible reinforcement. Round steel bars finally won general recognition as reinforcement as the question of increased tensile strength became more important. It was soon clear that the round steel bar did not represent the most suitable form of reinforcement for concrete in compression, and a number of limitations have therefore been specified.

These conditions were present during the time I spent in North America. In the beginning of the reinforced concrete era (1890-1896) a city engineer of Philadelphia, simultaneously with me, built a structure with girders of 20-ft. free span, and Ransome in San Francisco built girders of equal span. At that time nobody had the courage to use larger spans with ordinary reinforcing bars. In 1893 to 1894 I designed and built an arch bridge of 70-ft. span in Cincinnati, one of 100-ft. span in Stockbridge, Mass., and also used the Melan system in a number of other structures, which became the few representatives left for the rigid reinforcement which today is seldom used.

After a stay in Paris in 1900, I returned to Vienna and in 1902 I embedded a number of steel columns in concrete. The test results are published in my paper on column construction in *Beton und Eisen*, 1907, page 172, and in *Forscherarbeiten*, Heft 8, Berlin, 1908.

---

*A. C. I. Journal, Nov. 1930; *Proceedings*, Vol. 27, p. 263.
†Oberbaurat u. Dr. Techn. E. H., Vienna.

The difference between round steel bars and structural steel shapes as reinforcement for columns should not be considered merely as a difference in form; here occurs a fundamental distinction as regards difference in determination of the permissible load. The permissible load for columns of ordinary reinforced concrete is practically always determined from the equation:

$$P = (A'_c + A_s n) f_c \quad \ldots\ldots (1)$$

Where A'_c = the area of the concrete in the column
A_s = effective cross section of steel.
f_c = permissible compressive stress in concrete.
n = 15.

We see, therefore, that the permissible load is determined by the specified compressive stress in the concrete f_c. This stress appears to be so important that the whole construction depends upon it. It requires no great intelligence to show that this view-point has little justification, since the permissible compressive stress in the concrete can be exceeded without any dangerous results, and safety against failure is the only important item.

The other view-point, however, uses the ultimate strength as the determining factor, and demands such an arrangement of both materials that they work together and that both will be completely utilized until failure. The load at failure of the column is then:

$$P_{failure} = A'_c f'_c + A_s f'_s = P'_c + P'_s \quad \ldots\ldots (2)$$

Where f'_c = ultimate compressive strength of concrete
Where f'_s = ultimate compressive strength of reinforcement.

By means of a given factor of safety we arrive at the permissible load. This load is arrived at still more simply from the equation,

$$\text{Permissible load } P = A'_c f_c + A_s f_s = P_c + P_s \quad \ldots\ldots (3)$$

When both materials have their own factors of safety, the column has an average factor of safety which naturally depends upon which material predominates and which approaches the factor of safety for that material. In the beginning of the reinforced concrete era the possibility of full cooperation was questioned, and I made the tests of steel columns shown in Figs. 1 and 2 with and without concrete in order to show plainly how strengths are added. These figures are found in the fourth edition of my

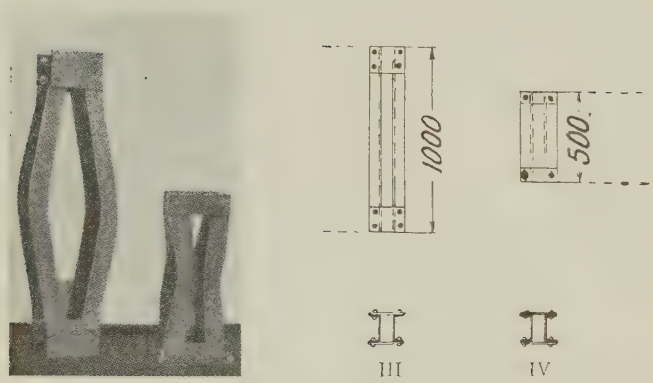

FIG. 1

handbook for reinforced concrete. It has been maintained that the materials will work together up to only 2 per cent reinforcement, but I have made tests with 12 per cent and believe that 20 per cent and more would work just as well with sufficient lateral reinforcement and sufficient strength of the concrete.

In 1910-1911 I made further tests with spirally reinforced steel and cast-iron columns and the results are published in Heft 3 of Reports of the Austrian Committee for Reinforced Concrete (see pages 57 and 116 *Beton und Eisen*, 1912), and found that by means of the lateral reinforcement even the highest compressive strength of steel was fully utilized in adding strength. From the deformation I derived the relation between the elastic carrying capacity and the strength addition, and, as at that time I could find no cheaper iron material than cast iron, I took especial interest in this material. Even though the war had already lasted for one year I was able to present the results of our work at the International Engineering Congress in San Francisco, 1915, and showed that the relation presented in Fig. 3 of the deformation of a column may be considered as the sum of two deformation curves. When the two areas in a reinforced concrete column correspond to A_c and A_s, and the corresponding load curves are P_c for the concrete and P_s for the steel, the addition of the two curves gives the actual deformation curve of the reinforced concrete column in the curve $P_c + P_s$.

This is a long-drawn-out introduction of the question which received almost 12 years interruption by the war and the hard times following the war, but it was necessary in order to go into the investigation which has been reported by Mr. Mensch.

In the first place I may say that it has not surprised me that the American cast iron shows so much lower strength than that used

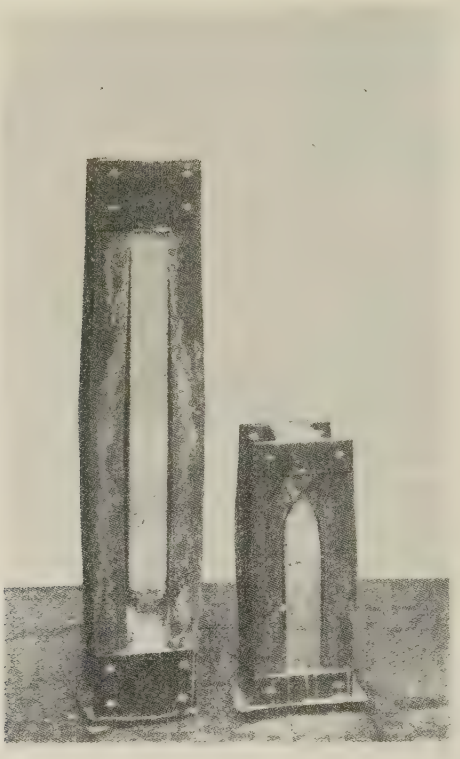

FIG. 2

in my Austrian tests. I have had the same difficulty with the German cast iron. The German and also the American foundries have no interest in producing a cast iron of high compressive strength. This is only a question of composition of the iron, primarily the carbon content. It is important to point out this fact since the question of the cost of producing cast iron with a compressive strength of 150,000 lb. per sq. in. plays no role even

though the ordinary cast iron has a strength of only 75,000 lb. per sq. in. In the specification (see Tetmayer) the minimum strength required for steel for buildings is always 100,000 lb. per sq. in. The Austrian foundries deliver cast iron which without special requirement has 150,000 lb. per sq. in. But in Germany one may get by with a material having a compressive strength approximately that of ordinary steel, that is less than 75,000 lb. per sq. in. (See the deformation curves published by Bach in Heft 3 of the Reports of the Austrian Committee).

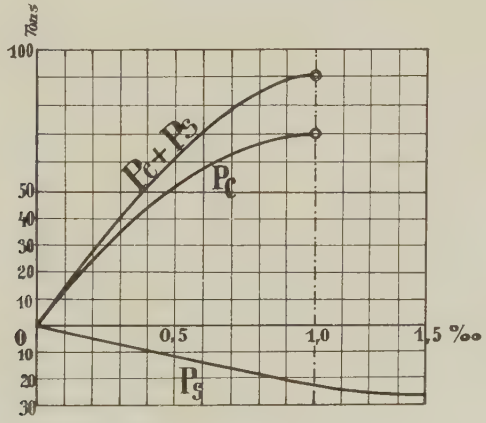

Fig. 3

Nevertheless it is important to note that the foundries have no interest in producing for the ordinary machine casting a material of high compressive strength, which naturally is much harder to work. When we in Austria have a cast iron of such a high compressive strength, it is due to the charge present in the foundries. When one in Germany wants a cast iron of high compressive strength he will have to find a foundry which happens to have a suitable composition. But if he requires a certain compressive strength from the foundry the operators do not know what price to charge for it. Since the use of cast iron for building purposes has practically stopped, they will have to make a special

charge for the work. For industrial use I believe that the situation for cast iron is the same in North America, and a study of the deformation curve would show that. The deformation curve for this kind of cast iron is quite flat and a high ultimate strain is required for the concrete, that is, a large amount of spiral reinforcement of high strength steel, in order to utilize the relatively low compressive strength.

In order to understand what important economical advantage the use of cast iron had in Austria before the war it must be remembered that I easily managed to utilize 100,000 lb. per sq. in. of a cast iron having a strength of 150,000 lb. per sq. in. by using a proper amount of lateral reinforcement, and could make use of permissible stresses up to 20,000 lb. per sq. in. However, when I used ordinary grade steel in columns I was governed by the specification which permits a maximum stress of 570 lb. per sq. in. in the concrete and 8,500 lb. per sq. in. in the steel, so that the utilization of the cast iron to double this amount, and more, would have reduced the reinforcement to one-half and less.

I want to mention that the conditions after the war have caused a considerable change. In Europe the cost of cast iron has increased relatively more than the cost of steel, and the most important factor is that while prior to the war we had to use a steel which at most had a yield-point stress of 34,000 lb. per sq. in., and a corresponding working stress of 14,000 lb. per sq. in., we have at present steel grades on the market with a yield-point stress of 47,000 to 53,000 lb. per sq. in. and permissible stresses up to 22,000 lb. per sq. in. Interest in the use of cast iron has therefore decreased considerably in Europe, especially on account of the official codes. The officials are not inclined to permit anything new, and certainly not anything they believe questionable. Cast iron can without doubt be poorly made and good cast iron requires careful manufacturing and rigid control.

The new methods of making cast iron produce excellent material, but the knowledge has not yet been acquired by the proper officials. It is illuminating in this respect that I have designed and built a number of important buildings and even

official projects in Austria and Czechoslovakia with columns of spirally reinforced concrete and cast iron. In Germany, however, where I designed arch bridges of this material with spans up to 250 feet, I was not permitted to make a single column of this kind, the only reason being the stubbornness of the building officials.

I cannot, however, explain the error limiting only to cast iron the viewpoint presented in the addition method given in equations 2 and 3. I have always made designs both with cast iron and with steel and left it to the contractor to decide which method to choose. We have even made far-reaching tests with high strength steel for the purpose of obtaining specifications for columns of steel skeletons. This work was published in March, 1931, as Heft 12 of the Reports of the Austrian Committee for Reinforced Concrete. In the following a short summary of these tests is given:

(1) The average deformation of ordinary concrete in a column amounts to 0.1 percent. This value will not be exceeded in a column with ordinary ties, showing that at failure the longitudinal reinforcement can not be utilized to more than 29,000 lb. per sq. in. whatever the yield point stress of the steel.

(2) For spirally reinforced concrete columns the shell outside of the spiral deforms with the column up to a deformation of 0.2 per cent. If only a small amount of spiral reinforcement is used (as is the case when the spiral is not intended to increase the strength but only for the utilization of the yield-point stress of the steel) the total cross section of the column can be used in the computation. It is not necessary to use only the area of the concrete within the spiral as has been common practice up to the present time.

(3) By the use of rigid structural shapes for reinforcement or of independent cast-iron columns, a direct increase in strength is obtained and the use of a small amount of spiral reinforcement will raise the strength as for the round iron reinforcement.

(4) These tests have recently proved the correctness of equations (2) and (3) regarding the "law of addition." With our limited means we managed to make 42 column tests during the summer of 1930. We aimed at a few typical examples and showed

how the strength of the steel column can be increased by 72, 108 and 172 per cent, by a simple embedment in concrete spirally reinforced. For such a skeleton half of the reinforcing steel can be saved by this arrangement which is so necessary with respect to safety against damage by fire. I have to my surprise read a circular from the American Institute of Steel Construction[1] wherein complaints are made against the fire insurance companies in the United States for specifying a thick concrete shell for steel frame buildings. This shell is considered only as dead weight. If this is dead weight they themselves are to blame because they evaluate the concrete so low. If they recognize that the concrete shell contributes to the strength, they can save half the steel weight by the utilization of an arrangement which is required anyway and so actually costs them nothing. I believe that this method will lead to a compromise between the competing methods of steel and reinforced concrete constructions. This method may be carried back to the early days of my stay in the United States nearly 40 years ago and I am glad to have been able to contribute my small share to the development of American building construction.

BY R. SALIGER*

Having made during the last years a great number of tests the Laboratory of the Vienna Technical College is in a position to add materially to the knowledge on composite columns. All tests were made very carefully as regards materials and methods in order to obtain that high degree of uniformity necessary for scientific comparison. The tests were made with columns of Dr. Bauer's system with cast iron skeleton and with hard steel bar skeleton.

(*A*) *Cast iron skeleton*—During 1928 tests were made on 48 columns partly of 47 in. and partly of 109 in. length. The columns were square or round, the hooping following the square or cylindrical form on the outside. The cast iron skeleton consisted of 4 bars having a total area of 5 sq. in., 10 sq. in. and 15 sq. in. respectively. The bars were of rectangular section and were held together by cast iron rings thus forming one rigid skeleton. The

[1] "Fireproofing Structural Steel," by Jack Singleton, published by American Institute of Steel Construction, 1929.

*Prof. Dr. ing., Vienna University Technical College.

cast iron core was from 4.6 to 15.3 per cent of the total area inside the hooping. The spiral consisted of round mild steel wire of 0.2 in., 0.28 in. and 0.4 in. diameter respectively at 1 in. to 4 in. pitch. The spiral was from 0.5 to 4 per cent of the hooped area. The concrete mixture was 1 part cement to 4 parts sand, cube strength being 2,870 lb. per sq. in. and cylinder strength 2,020 lb. per sq. in., age 15 days.

The ultimate strength of the cast iron core was 113,600 lb. per sq. in. Tests of all spiraled columns showed that with very slight variations the ultimate strength is given by the formula:

$N_{ultimate} = F_k \sigma_p + F_g \sigma_g + 2.2 F_s \sigma_s$

F_k = hooped concrete area

F_g = area of case iron core

F_s = equivalent area of spiral reinforcement.

σ_p = cylinder strength of concrete 2,020 lb. per. sq. in.

σ_g = utilizable resistance against compression of cast iron 68,160 lb. per sq. in.

σ_s = yield point of spiral wire.

According to results obtained the total resistance to compression of the cast iron core was utilized up to 63 per cent. The long columns carried at failure 15 per cent less than the short ones.

(*B*) *Hard steel bar skeleton*—During 1929 and up to 1931 four series of tests of columns from 47 in. to 120 in. long were made at the Vienna and Berlin laboratories. (Technische Versuchsanstalt Wien und Material Prüfungsanstalt, Berlin).

The spiral hooping of all columns was 12 in. in diameter, the outside diameter of the columns being 13.4 in to 13.8 in. The spiral consisted of round wire from 0.2 in. to 0.28 in. diameter at 1 in. to 2 in. pitch. Flat iron hooping was also used. The spiral was from 0.5 to 2.0 per cent of the hooped area. The hard steel bars had a tensile strength from 113,600 lb. to 142,000 lb. per sq. in and a yield point in compression of 106,500 lb. per sq. in. The diameter of the longitudinal bars was from 1.2 in. to 1.7 in.; their number varying from 4 to 6 in each column. The metal area of the core represented from 3.8 to 11.2 per cent of spiral area.

There were 10 to 20 columns tested in each series. By selecting sand and gravel of good quality and by careful mixing great uniformity and quality of the concrete was obtained throughout. Otherwise the results would scarcely have formed a sufficiently reliable base for comparison.

We may arrive at the ultimate strength of the columns, with very slight variations, as follows:

$N_{ultimate} = F_k \sigma_p + F_e \sigma_e + 2.9 F_s \sigma_s$

σ_e = yield point of the longitudinal steel bars embedded in hooped concrete = 113,600 lb. per sq. in.

The efficiency of hooping turned out to be 2.9 times the efficiency of longitudinal reinforcement with material of the same quality and weight. The utilizable resistance against compression of hard steel core was 113,600 lb. per sq. in., thus being greater by 6 per cent than the actual yield point in compression of the naked steel bars.

By comparing the results of four series of tests the following conclusions were arrived at:

1. The strength of the metal core will be fully utilized if the spiral represents 0.5 per cent of the hooped area.
2. Increasing the hooping results in an increase of the resistance of hooped concrete only.
3. Columns 120 in. long show a carrying capacity 15 per cent smaller than that of columns 47 in. long.
4. The utilizable resistance to compression of columns with steel bars welded of two pieces is 10 per cent less than that of columns with bars in one length, not welded.
5. The carrying capacity of the columns is determined by the combined resistances to compression of the concrete core, of the metal core and the tensile strength of the spiral.
6. With small loads the hooped concrete and the metal core remain one solid mass. With big loads the outer layers crack and fall off sooner or later before the stress at failure is reached, according to strength of the metal core.

(*C*) *Structural steel skeletons*—Recently 10 columns with structural steel skeletons, spirals and concrete were tested. All columns were 120 in. long, had octagonal form and 13.8-in. out-

side diameter. The structural steel core consisted of two channel sections, 4 in., 6 in. and 7 in. in depth, held together by gusset plates. The spirals consisted of bars 0.2 in. and 0.28 in. thick at 2 in. pitch. The yield point of structural steel was from 35,220 to 37,200 lb. per sq. in. The tensile stress of the spiral wire was from 35,500 to 39,800 lb. per sq. in.

The concrete mixture of 1:5 resulted in a cube strength of 2700 lb. per sq. in. and a cylinder strength of 2100 lb. per sq. in. at 30 days.

All tests gave extremely uniform results regarding load at cracking of outer layers and load at failure. Loads at cracking were from 4.7 to 13.1 per cent under maximum loads.

At failure the stress in the concrete was estimated equal to the cylinder strength. Stresses in the structural steel were 10 per cent greater than the above mentioned yield point. No sideways buckling was observed.

Most columns are so short that the spirally reinforced concrete would fail before the column buckled. The strength of such a column would be the summation of the strengths of the spirally reinforced concrete plus the load borne by the cast iron at the ultimate strain of the spirally reinforced concrete, unless the per cent of cast iron is unusually high.

BY JOHN TUCKER, JR.*

The concrete column reinforced with spiral and cast iron that may be justly termed the Emperger column has proven of merit in actual construction. Mr. Mensch is to be congratulated upon his sustained interest in presenting information and obtaining data on this type of column.

The tests that have been made upon columns of this type unfortunately have given insufficient data upon which to obtain constants based on a sound theoretical analysis. In particular, the control specimens that would give the strength of the concrete in the reinforced columns are very meager. The ultimate strain and the modulus of elasticity of the spirally reinforced concrete up to the ultimate strain should be known. The Emperger columns tested in the United States have had flat ends bearing directly upon plates on the platens of the testing machine. The amount of

*Bureau of Standards ,Washington, D. C.

motion of the spherical bearing under such conditions is small, and the tests approximated the condition of fixed ends. The movement that did occur[1], however, confused to a considerable extent the conclusions that might be drawn from the tests.

If, instead of empirical equations that hold for each set of tests only, as have been obtained, completed data were secured upon columns tested with definite end conditions, the critical length (for buckling) could be computed by the Engesser-Considere theory[2]. It is regretted that this splendid column theory which has been experimentally confirmed[3] for cast iron has not been applied to the interesting Emperger type; and it is also to be regretted that the theory is not familiar to more engineers in the United States.

Mr. Mensch gives values of .001 and .01 for the ultimate strain of plain and spiral reinforced concrete; these values are approximately correct but may be sufficiently misleading to warrant correction.

The average ultimate strain of unreinforced concrete[4] is approximately .0014 in. per in., the individual readings varying from .0010 to .0018, approximately. The ultimate strain of the spiral reinforced column is under .008 in. per in., some experimentally obtained values being as low as .003. The test data indicate that the higher the per cent of spiral reinforcement the greater the ultimate strain.

AUTHOR'S CLOSURE

Prof. Dr. R. Saliger contributes the result of about 100 tests on composite columns. It is gratifying to note that not once in his discussion does he make use of the ratio of the moduli of elasticity of metal and concrete, commonly denoted by n. The reason is that the strength of reinforced concrete cannot be explained by the use of n which changes in value at every change of loading.

This discussion contains also a clear cut statement that the action of the spiral hooping is proportional to the yield point of the wire, a truth appreciated by very few engineers. The tests on

hooped columns with square spirals which proved to be nearly as efficient as round spirals are new to American practice.

Although the cast iron used in Dr. Saliger's tests was of lower strength than that used by Dr. Emperger the ultimate stress per sq. in. was higher than in the American tests because of the very low value of the l/r of the cast iron skeletons. The series B of Dr. Saliger's tests with skeletons of high carbon transmission shaftings is very instructive in view of the fact that many city codes and specifications do not permit higher stresses on high carbon bars than on medium steel bars. After giving the hooped concrete in this series all possible credit for the strength it contributed, the remaining part of the ultimate load divided by the area of the steel skeleton amounted to 113,600 lb. per sq. in., which is 6 per cent larger than the yield point. Here we attribute to steel bars a stress of only 30,000 lb. per sq. in. at the ultimate load and consider high carbon bars of no advantage in columns. These tests ought to be effective in dispelling this error.

Series C with structural steel cores gave nearly identical results with the columns 11 to 14, made by the writer, and shown in Table 4.

Mr. Molitor's discussion[1] is answered by Dr. Saliger's and Dr. Emperger's discussions.

John Tucker, Jr., who did the actual testing of the Emperger columns at the Bureau of Standards' Pittsburgh Laboratory in 1916, voices regret in his discussion that no attenpt has been made to obtain data for a sound theoretical analysis of composite columns. The writer wishes to emphasize that, notwithstanding the fact that thousands of extensometer tests have been made on simple concrete beams, (which tests show to be nearly twice as strong as the accepted theory teaches), we have no reliable data to explain their behavior, and all the extensometer tests made on spiral columns have not taught American engineers to use only high elastic limit steel for spiral and vertical reinforce-

[1] A. C. I. Journal, March 1931; *Proceedings*, Vol. 27, p. 947.

ment, and that all our positive and valuable knowledge of the strength of materials consists of more or less empirical data, derived from practice or tests. The modulus of elasticity of concrete varies greatly after ½ of the ultimate strength is reached, as it does for cast iron, while the common theory which assumes a constant modulus of elasticity leads engineers astray and prevents them from adopting new combinations of materials.

Discussion of paper by M. O. Withey:

"Some Long Time Tests of Concrete"*

AUTHOR'S CORRECTION

P. 549, in the ninth line from the bottom of the page, change *25 deg.* to *— 25 deg.*

P. 559, in the first column of Table 5, third line below headings, change *expansion* to *contraction.*

BY W. K. HATT

Professor Withey's paper on "Long Time Tests of Concrete" contains Fig. 8, showing the relation between volume-change and loss or gain of water in curing.

The diagram in my Fig. 1 shows these relations from the several series of tests performed in the Laboratory for Testing Materials of Purdue University during the last two or three years. The notations on the figure give information of the nature of the aggregate, the concrete mix, etc.

It is apparent that the law connecting change of weight, resulting from gain or loss of water, and change of length, obtained by strain gage measurements, is not a straight line relation. This relation varies with the richness of the mix.

The duration of constant immersion or constant air drying as represented in Fig. 1 varied from 24 hr. to 130 da. at which latter time the specimens had closely approached a period of equilibrium.

The zero hour of beginning the measurements was 24 hr. subsequent to a period of 24-hr. curing of specimens in a damp atmosphere.

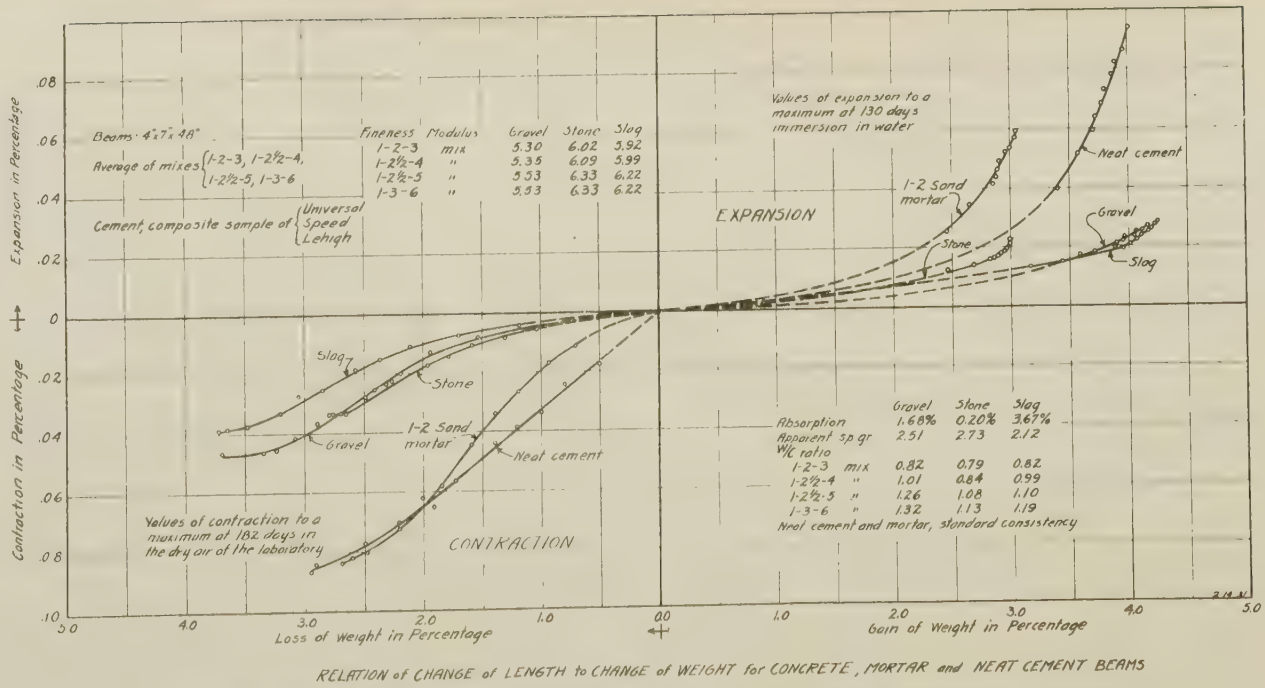

FIG. 1 RELATION OF CHANGE OF LENGTH TO CHANGE OF WEIGHT FOR CONCRETE, MORTAR AND NEAT CEMENT BEAMS

CONVENTION DISCUSSION

M. O. WITHEY—I would like to suggest that the coordinates to this curve, Fig. 1, are not the same as shown in my Fig. 8. In my Fig. 8, I show loss of water in gallons per sack of cement. Professor Hatt's figure shows loss or gain as a percentage of the weight of the sample of concrete. If his figure is changed so that the coordinates agree with those shown in my Fig. 8, I think there will be more marked agreement in the two sets of data.

BY DUFF A. ABRAMS

A study of concrete strengths by the same organization and on the same cement over a period of 20 years is unique in engineering literature. I wish to congratulate Prof. Withey on this excellent report. I hope he will be here to present the final report when the 100-year tests are completed.

At the Lone Star Research Laboratory in New York City, we have carried out during the past few months, an extensive series of compression tests of concrete using:

2 cements
6 mixtures
3 consistencies for each of above conditions
6 ages at test (others to follow)

Our tests have a direct bearing on certain phases of Prof. Withey's work. I wish to speak particularly of the age-strength relation for concrete made of cements of different characteristics using a wide range of mixes and consistencies and to call attention to other significant phases of these tests.

The speaker pointed out in 1918[1] that the strength of concrete was a function of the logarithm of the age at test. This conclusion was based on tests from many American and European laboratories which were available in the literature at that time. The recent tests referred to above have shown that this logarithmic relation is not general for all cements, mixes and consistencies. The logarithmic relation was true for the cements and mixtures used a dozen years ago, but does not apply to modern cements

[1] "Effect of Age on Strength of Concrete" by Duff A. Abrams, *Proc.* A. S. T. M. Part II, 1911, p. 317.

and the richer or drier mixtures (that is concrete of the lower water-ratios).

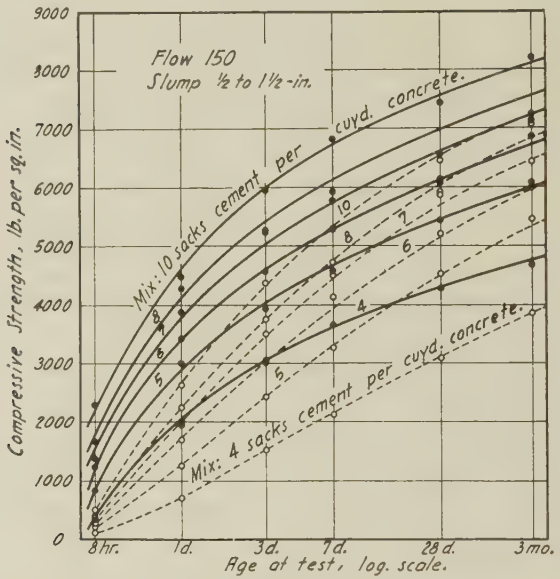

FIG. 1—AGE-STRENGTH CURVES FOR CONCRETE OF FLOW 150 PER CENT

Compression tests of 6 x 12-in. cylinders cured in moist room.
Sand and gravel aggregates.
Each point is the average of 2 tests.
Solid curves, High-Early-Strength Portland Cement.
Dotted curves, Ordinary Portland Cement.

Figs. 1, 2 and 3 show age-strength curves for concrete ranging in cement content from 4 to 10 sacks per cu. yd. of concrete. Compression tests were made on 6 x 12-in. cylinders cured in moist room. Each figure is for concrete of a definite flow as measured by 15 ½-in. drops of the 30-in. flow table. The solid lines represent the high-early-strength cement; the dotted lines, ordinary portland.

Many will recall that formerly little attention was given to concrete strength at ages earlier than 28 days; later we became more venturesome and made tests at 7 days; lately the test

Each value is average of 2 tests.
Same tests as in Figs. 1, 2 and 3.

periods have been reduced to 3, 2 and 1 day and now tests are regularly made as early as 8 hours.

It is only the leaner mixes of ordinary portland cement which give essentially straight lines when plotted to a logarithmic scale of ages. It is interesting to note that relation holds for test periods as early as 8 hours. As soon as we get into the richer mixtures and drier consistencies (low flow) the lines curve upward sharply and depart materially from straight lines. The modern cements and richer mixtures have a rate-of-increase-in-strength at early periods which is much higher than the older cements and leaner mixtures which were prevalent a dozen years ago. This high rate has the effect of throwing the curves much higher on the scale—too high for the logarithmic relation to hold.

Figs. 4 and 5 are the same tests plotted with reference to the water-ratio of the concrete; separate curves are drawn for each age. These curves are in the form with which you are familiar and show that both cements give water-ratio strength curves of exactly the same form. The only difference is in the age at which a given cement reaches a designated position on the diagram.

If now we plot the curves in Figs. 4 and 5 to a logarithmic scale of strengths we find a very interesting relationship as shown in Fig. 6. All of the water-ratio curves become straight lines regardless of type of cement or age at test and they all intersect the ordinate for zero water at a single point marked A.

The equation of all these curves may be written in the form

$$S = \frac{A}{B^x}$$

where S = the compressive strength
x = water ratio (an exponent)
A and B are constants

This is the same equation which I used in 1918 in the original publication of the water-ratio law[2] for concrete strength. It was then stated that "A and B are constants which depended on the quality of the cement used, age of the concrete, curing conditions, etc." It was my original thought that each cement had a dis-

[2] "Design of Concrete Mixtures" by Duff A. Abrams, Bulletin 1, Structural Materials Research Laboratory, Lewis Institute, Chicago.

tinctive value for A, however these tests give an entirely different view and suggest that A is an *invariant* which is common to all portland cements and that B is quantity which varies with quality of cement and the age at test. As the quality of the

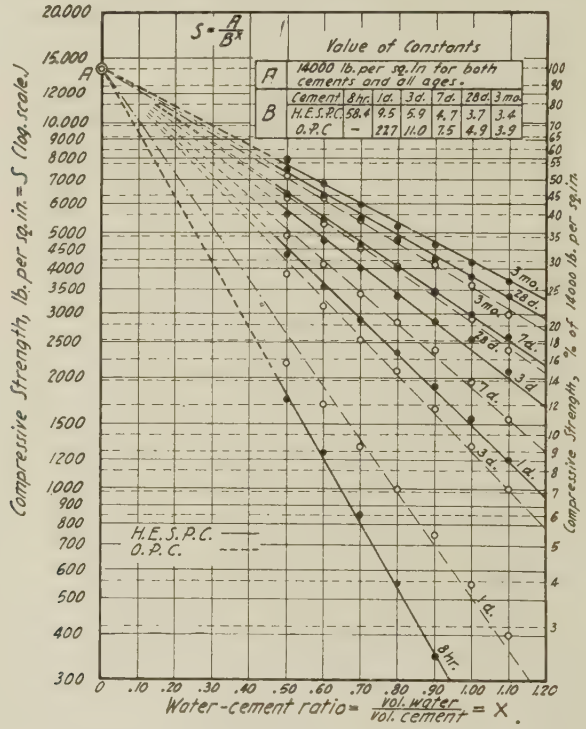

FIG. 6—WATER-RATIO—STRENGTH CURVES FOR CONCRETE
Same curves as in Figs. 4 and 5, strengths plotted to a logarithmic scale.

cement or age at test increases the value of B becomes smaller. B is the slope of the curves on this diagram.

All of the water-ratio strength curves in Fig. 6 are seen to be rotating about the point A. The quality of cement (as measured by B) simply *dictates the age at which a given strength will be reached.* In other words cement quality may be defined in terms of a rate of increase in strength at early ages.

That A is a most interesting invariant is indicated by the fact that it is the same (14,000 lb. per sq. in.) for the modern cements

as for the cements tested 15 years ago. It is no accident that Prof. Withey's tests give this value for A when plotted on our Fig. 6.

The point A is in itself an absurdity, since it is a concrete strength for a zero water-ratio; however it does have a real significance in indication of a "ceiling" or ultimate strength which all concretes, of whatever grade of portland cement, mixture or water-ratio approach, so long as they do not dry out.

My interpretation of the significance of A is that it is impossible to mold concrete under gravitational forces only which will develop strength greater than 14,000 lb. per sq. in. This, of course, applies to 6 x 12-in. cylinders and to the particular routine of testing which is now commonly followed. The consolidation of concrete under pressure appears to give a much higher "ceiling."

The tests in Bulletin 1 referred to above gave $B = 7$ at 28 days for ordinary portland cement. The table in Fig. 6 gives for ordinary portland cement $B = 4.9$ at 28 days and $B = 7.5$ at 7 days. The modern "ordinary cements" give strengths at about 9 days equivalent to the 28-day strength of the cements manufactured 15 years ago; the high-early-strength cement gives the same strength at about 2 days.

Each point on Fig. 6 represents some combination of cement quality, water-ratio and age. These are the 3 factors which go to make up concrete strength.

The scale at the right of Fig. 6 enables us to read off the percentages of the "ceiling" strength reached at any water-ratio or age; for example with a water-ratio of 0.80, ordinary portland cement has 7 per cent of its strength at 1 day; high-early-strength cement has 17 per cent. At 7 days we have 21 per cent and 28 per cent. For higher water ratios the spread between the two cements is greater and at lower water-ratios the spread is less than the values given.

The *time element* is of fundamental importance and appears to be the only real difference in concretes made and tested under standard conditions and cured damp.

The exact causes for this definite "ceiling" in concrete strength of portland cements are not clear. There are not many reports of tests which throw light on these questions, due to limited range in water-ratio, age, etc. Further studies will undoubtedly throw much new light on many features of concrete properties and behavior.

Readers are referred to the JOURNAL *for December 1931 (Vol. 28), for further discussion which may develop. Such discussion should reach the Secretary by Nov. 1, 1931.*

Behavior at high temperatures of concrete containing blast furnace slag. RICHARD GRUN AND HUGO BECKMANN. *Archiv fuer das Eisenhuettenwesen* (Germany), May, 1930, V. 3, No. 11, p. 677-83.—The statement confirms itself that quartzous aggregates are less suitable for concrete which is exposed to high temperatures. It was found that concrete made with blast furnace slag shows least decrease in strength under heat treatment. Slag may be mixed with cement or used as aggregate in concrete. It seems that the best concrete for high fire resistance can be made from dense, strong slag as aggregate by use of the voids-curve or Fuller curve and by use of cement containing blast furnace slag.—A. E. BEITLICH

Corrosion of steel by breeze and clinker concretes. *Dept. Sci. Ind. Res., Special Report* No. 15, (England).—Instances have been reported of serious corrosion of steel in contact with breeze and clinker concretes, which are much used because of low density and cheapness. Tests undertaken to investigate these effects included an examination of behaviour of solutions derived from action of moisture on various types of coal residue aggregates. Since it has been found that corrosion may be rapid even under dry indoor conditions, examination was made of the corrosive power in moist air but out of contact with the sources of liquid moisture. Also tests were made to ascertain relation between permeability and corrosive power, and the effect of replacing fines in breezes and clinker aggregates by sand. It is considered that sulphur content of the materials is prime cause of corrosion and that porosity and permeability are of minor significance in this connection. Accounts are given of the various tests, and the particular properties of coal residue aggregates responsible for corrosion with their relative importance are indicated.—JOHN E. ADAMS

New Pycnometer measures free moisture in aggregates. D. D. McGUIRE and W. H. ROWAN. *Concrete*, May, 1930, V. 36, No. 5, p. 41.—Change in Tennessee highway department specifications for control of proportions of fine and coarse aggregate by weight made it evident that one of major factors of this type of control was accurate knowledge of correct per cent of free moisture in aggregates and their apparent specific gravity. New type pycnometer was developed from several revamped pieces of equipment for this purpose. Container, is made of non-corrosive, metallic material, such that its base is 10 in. in diameter and top 3 in. in diameter. Height is 12 in. Under bottom are placed three round points of contact with weighing table of a solution balance. To determine apparent specific gravity, it is only necessary to determine weight of can and bar, water which can will contain to point where moisture gauge bar touches its surface, and weight of sample under

consideration. To determine free moisture, apparent specific gravity, G_s, in saturated and surface-dried condition, and apparent specific gravity, G_w, in a wet or stock-pile condition, are required. From formula, $\frac{G_s - G_w}{G_s \times (G_w - 1)} \times 100 = M$, the per cent moisture may be readily obtained.—C. BACHMANN

Use and abuse of building materials. A. M. GILES, *Builder* (England), June 6, 1930, and June 13, 1930, V. 138, No. 4557, and No. 4558, p. 1099 and 1149.—Concrete: The historical development of the use of concrete is outlined and reference made to the greater lasting quality of concrete as compared with stone. For aggregate any hard substance may be used, although cinders are not recommended owing to corroding effect on the steel. It is recommended that sand be screened from gravel and remixed to ensure proper proportions. Limestone is liable to decomposition under great heat and is not suitable for fireproof work. Essential quality of all aggregates is cleanness and freedom from earthy matter. This should be tested by allowing sample to stand in water for a time. Dirt will collect on the top of the aggregate as a film. A sample may also be tested by shaking up with weak solution of caustic soda and allowed to stand for 24 hours. If solution above aggregate is brownish yellow too much impurity is present. Broken brick should always be well cleaned and soaked in water before mixing. In parts where washed aggregates are not obtainable, it is often advisable to fit up washing and screening apparatus combined, on site. For non-porous concrete coarse aggregate should pass a ¾ in. ring and be retained on a ⅛ in. mesh. Aggregates: For dense concrete voids must be filled; sand as well as shingle should be well graded. Too much dust in aggregates causes weak concrete since more water is required for mixing. Scientific proportioning and right consistency should be aimed at. Too dry mixes, though strong, are porous, while wet concrete takes long to set and is weaker. Methods of arriving at proper proportioning are outlined, and reference is made to the fineness modulus method of proportioning by analysis.—JOHN E. ADAMS

CEMENT

Determination of the specific gravity of cement. KARL E. DORSCH. *Tonind. Ztg.* (Germany), May 8, 1930, V. 54, No. 37, p. 627-8.—For rapid but accurate determination of specific gravity of cement a large mouth pycnometer with a long graduated, ground-in tube ending in a small funnel is used. One hundred g. cement is introduced into pycnometer which is stoppered and shaken thoroughly. Then more C_6H_6 is introduced from a burette to give an accurate measure of volume after temp. adjustment is made.—F. O. ANDEREGG

Cement. *Contr. Jour.*, June 25, 1930, V. 102, No. 2663, p. 2058.—Presence of coal in breeze aggregates may cause failure in cement renderings on concrete made with them, as well as in the concrete itself. The effect of an excess of sulphides in basic slag aggregates is not marked in dense and impermeable concrete, though its effect is very evident in plain and reinforced concrete. Calcium sulphate combines with calcium aluminate in the cement and forms calcium sulpho-aluminate, and causes disintegration. Swelling and cracking in cement rendering on brick work may be caused by sulphuric anhydride in the bricks. Concrete roads have been known to fail in same way through absorption of this compound from road sub-base composed of stone and slag. Ground waters near coal deposits, tanning liquors, fatty acids, creosote and sugar tend to disintegrate concrete exposed to their action. Whin chips and whin dust result frequently in failure to harden—due perhaps to excessive water required to wet the dust in mixing. River gravel, when coated with algae may not bond well with cement.—JOHN E. ADAMS

Lehigh Valley cement plant operates on America's pioneer mill site. *Pit and Quarry*, May 7, 1930, V. 20, No. 3, p. 36-37, 33 ill. Explains David O. Saylor's portland cement project in 1866, his patent in 1871, and the use of his product more than 50 yrs. ago in constructing the Eads jetties at mouth of Mississippi River. Coplay Portland Cement Co. is direct successor, occupies original site, and quarries from same deposit. At this plant can be found the old fashioned, dome-type lime kiln, high vertical kiln, and improved rotary kiln. Originally rock and clinker were ground with buhr stones. This is the first cement plant to be electrically operated. Limestone deposit is about 6 mi. north of Allentown, near Coplay, Pa. It produces almost pure calcium carbonate and an argillaceous stone, each kind running uniform in color and quality. Quarry has been worked 25 yr. The face is 180 ft. high and the floor has an area of about 7 acres. Lower levels are being started. On a jig-back cars of stone are hauled up 400-ft. incline, one at a time, by an electric hoist. Primary gyratory crusher reduces the stone to 3-in. This stone is hauled in trains of 12 cars to main plant by a 16-ton gasoline locomotive. Cars are dumped by hand over a rectangular concrete 2,000-ton bin. Following 54-in. by 24-in. roll crusher, flow sheet includes magnetic separators, pulverized-coal-fired rotary dryers, automatic proportioning scales, a hammer mill, 18 fine-grinding mills, storage and blending tanks, 4 steel kiln-feed tanks and four 125-ft. kilns using pulverized coal as fuel.—A. J. HOSKIN

A thermal study of the manufacture of cement. H. LEFORT. *Rev. materiaux construction trav. publics.* (France) 1930. No. 248, p. 171-6.—Another heat balance calculation.—F. O. ANDEREGG

The properties of the cement bacillus and its development during disintegration of concrete in sulfate waters. A. GUTTMANN and F. GILLE. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 46, p. 759-62.—There can be no doubt about existence of calcium aluminum sulfate as the cement "bacillus." The best protection consists in making a dense and rich concrete. —F. O. ANDEREGG

Viscosity of setting cement. Immersion filter method. K. E. DORSCH and A. DEUBEL. *Kolloid Zeitschrift* (Germany), April, 1930, V. 51, No. 1, p. 180-6.—Investigations were carried out at Institute of Technology in Karlsruhe (Germany) concerning viscosity of cement mixed with water for normal consistency. Tests made with usual method did not give reliable results on account of sedimentation. New immersion filter method was derived, which allows measurements of viscosity of cement during period of setting with accuracy of 5 per cent. Progress of setting of a number of different cements was studied. During the first time of setting (0-60 min.) viscosity increases rapidly. This period is followed by constant viscosity for ½ hour. After this time viscosity increases again. Results of experiments agree with theories of setting.—A. E. BEITLICH

Annual meeting of German Portland Cement Manufacturers Association, March, 1930. *Zeitschr. angew. Chem.* (Germany), May, 1930, V. 43, p. 355.—The following papers were presented: (1) Gustav Haegermann: Sintering of cement raw materials. Rate of combination in burning cannot be judged from appearance or shrinkage of clinker. Best temperature for sintering of cement raw materials is between 1275° and 1295° C. (2) Eitel: Hydrates of tricalcium-aluminate. Thorvaldson's results on disintegration of cement by sulphate waters are discussed. (3) W. A. Roth: Thermochemistry of cement. Heat of reaction, which is formed when cement raw mix is burned with paraffin and compressed oxygen in a calorimeter, was calculated. Investigations were made to study heat of formation and heat of setting by dissolving cement raw mixes in hydrofluoric and hydrochloric acid. (4) Hans Kuehl: Relation between strength of cement and fineness. Tests indicated that strength of cement does not increase appreciably when particle size drops

below 20 microns. Suggestions are given for manufacture of high strength cement by certain combinations of particle sizes. (5) F. Krauss: Importance of complex compounds. (6) H. Burchartz: Effect of storage on cement. Discussion of the theory by Gensbaur. (7) R. Nacken: Heat of formation of silicates. Heat of solution was determined by dissolving in mixtures of hydrochloric, hydrofluoric and nitric acid. (8) L. Forsen: Gypsum and other retarding agents. Theory of setting and hydration of cement is presented. (9) Otto Graf: Concrete disintegration in aggressive waters. Paper discusses resistance of different kinds of cements against aggressive waters. Influence of fineness is cited and suggestions for concrete protection are given. (10) A. Hummel: Fineness modulus of aggregates. (11) A. B. Heller: Improvements in mill practice. New type of mill for closed circuit grinding is described.—A. E. BEITLICH

The first Dutch cement works, at Saint Pietersberg, near Maestricht. *Revue Materiaux Construction trav. publics* (France), Jan., 1930, No. 244, p. 19-23.—This is a works for treatment of chalky marl obtained at Saint Pietersberg, and turns out annually 300,000 tons of cement. (1,000 tons of clinker per diem). The chalky marl is treated together with imported plastic clay (levigation). The powdered material and the slime are transported with the aid of pneumatic apparatus. All the most up to date implements are used for crushing, grinding and mixing process. Coal is also dried and treated with success.—A. SIZE

Enlargement of the Portland Cement Works at Groschowitz (Upper Silesia). *Revue Materiaux Construction trav. publics* (France), Feb., 1930, No.245, p. 74-76. A description of alterations to cement works in Upper Silesia (manufacturing artificial portland cement by the wet process) to increase production from 200 tons to 500 tons per day. Works are easily controlled and output very regular. Nearly all the machinery is operated individually. —A. SIZE

Suggestions for selection of lining for cement kiln, especially for rotary kiln. OTTO FREY. *Zement* (Germany), May, 1930, V. 19, No. 21, p. 492-3.—In selecting suitable linings for cement kilns it is necessary to make chemical analysis of raw material and firebrick. Clinkering point and melting point must be determined. Clinkering point of lining must be more than 50° C. higher than clinkering point of raw mixture.—A. E. BEITLICH

The rotary kiln and waste heat boiler. S. STEINER. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 52, p. 858-60. A review of the arguments for and against the waste heat boiler in connection with the rotary kiln.—F. O. ANDEREGG

Portland cement plant "Kursachsen" in Carlsdorf (Germany). *Zement* (Germany), May, 1930, V. 19, No. 20, p. 464-7.—Plant was built in 1928 in Carlsdorf a. U. near Naumburg a. S. and was enlarged in summer 1929. Output is 500 t. daily. Location of plant is favorable with water way connections to northern and central parts of Germany. Raw materials are limestone and clay. Quarry is situated 500 m. from the plant. Stone is transported by aerial tramway to crusher; discharge of cars is automatic. Belt conveyer delivers crushed materials to raw mill, where both raw materials are stored in bins. Two table feeders at bottom of bins control mixture. Both feeders are driven by same motor, speed of which can be regulated. Raw mixture and water enter two three-compartment-mills. Two special bins with table feeders are installed to add admixtures for manufacture of special cements. Slurry runs to four concrete tanks with conical bottoms. Elevator buckets transport slurry from outlet of tanks to distribution arrangement on top. Compressed air provides good mixing. From there raw mixture is delivered to kiln feeders which are regulated by individual motors. Plant has two Unax kilns with coolers. Two finishing mills, each one having four chambers, are used for cement grinding. Screws and elevators bring finished cement to four storage

bins of reinforced concrete. These are provided with flat bottoms, and cement is moved from bins to packers by pumping system. Latter enables mixing cement from different bins. Coal arrives at plant in carloads and is fed directly to crushers. Conveyer belt carries material to two coal dryers and storage bins. Special consideration is given to perfect dust precipitation. Power of 30,000 volts is furnished to plant from outside and is transformed to 500 volts in own power station. Plant equipment and machinery were installed by F. L. Smidth & Co. A/S, Kopenhagen and Luebeck. Several photographs accompany article.—A. E. BEITLICH

Cement chemistry in theory and practice. "Zementchemie in Theorie und Praxis." HANS KUEHL. 1929. Editor: *Zement und Beton*, G. M. B. H., Berlin, 92 pages. R. M. 4.50. Reviewed in *Zement* (Germany), May, 1930, V. 19, No. 18, p. 432.—Subjects of book are: ways of cement research, theory of cement burning, constitution of clinker, hardening problem and chemistry and technique of high early strength cements. Book is of great value to cement research workers and cement manufacturers.—A. E. BEITLICH

Heat of mill and setting time of cement. K. KOYANAGI. *Zement* (Germany), May, 1930, V. 19, No. 20, p. 467-9.—Investigations were carried out in Japan with gypsum which was heated at temperatures from 130-200° C. for half an hour. Content of SO_3 and loss on ignition were determined. Treated gypsum was mixed with clinker in proportions from 0.9-2.5 per cent SO_3. Setting tests showed that setting time decreases with increasing temperature of heating gypsum. When SO_3 content is lower than 1.2 per cent, cement never shows quick set. Difficulties were overcome by keeping SO_3 content between 0.9 and 1.2 per cent. (cf. *Zement* (Germany), Nov., 1929, V. 18, p. 1348-50; *Journal Amer. Concrete Inst.*, Jan., 1930, p. 3.)—A. E. BEITLICH

Rotary kiln calculation. A. B. HELBIG. *Zement* (Germany), May, 1930, V. 19, No. 19, p. 440-4.—Author gives detailed calculation of heat economy of rotary kiln and discusses following points: heat consumption for burning off carbon dioxide of raw mixture, for vaporization of water, heat loss due to conduction and radiation in kiln and cooler and heat of formation of clinker. Utilization of rotary kiln waste gases can be made very economical when difficulties caused by dust are overcome. Automatic recording thermometers and carbon dioxide meters should be installed on every kiln. Conditions are cited which lead to wrong registrations on those apparatus.—A. E. BEITLICH

Power and heat economy in cement industry. Directions for examination and valuation of kilns and burning processes. JAKOB KOCH. *Zement* (Germany), April, 1930, V. 19, No. 14, 15, 16 and 18, p. 324-8, 348-53, 373-7 and 418-23.—Burning process in cement kiln consists of number of separate processes. Author illustrates operating conditions by means of graphs. Dry and wet processes are discussed. Formulas are given for calculation of heat consumption, amount, temperature and heat content of waste gases and their dependence on the operating conditions. Relations are shown between amount of waste gases, heat consumption and excess of air and suggestions are made for economic utilization of waste gases. Efficiency of waste heat boiler system is calculated for dry and wet process, and influence of vapor pressure on economy is illustrated. Several tables show amount of waste gases and their temperature in both processes by different heat consumption and also necessary amount of heat for vaporization of water dependent upon water content in raw material. One single diagram is given which shows amount of gases for fuels with any calorific value, any coal consumption and any excess of air. Same diagram enables one to read heat content of waste gases, their temperature and preheating temperature of combustion air for any heat consumption for burning of dry raw mix, for any water content in raw mix and for any loss in heat by radiation and in clinker. A number of examples of practice are given which illustrate the use of these diagrams.—A. E. BEITLICH

Importance and evolution of the concrete industry in Italy. ANTONIO PESENTI. *L'Industria Italiana Del Cemento* (Italy), Dec., 1929, p. 4-5.—Cement industry started in Italy at about same time as in United States and at first proceeded on an empirical basis with correspondingly poor product. Wars and political vicissitudes retarded development, despite presence of abundant raw material, until 1870 when national unity was achieved. First plant for production of artificial portland cement was built in 1873, followed rapidly by numerous plants in Casalese, Bergamasco, Veveto, Emilia, Toscana, Umbria and elsewhere. In 1904 discovery of rich beds of marl led also to erection of plants along the Adriatic coastline. In 1898 and 1904 there were severe depressions but in 1904 began a period of prosperity which ended with the World War. Old plants were enlarged and new plants constructed and scientific methods were introduced. After the war there was great expansion of cement industry so that it now is one of most important industries of country representing a capital employed of 1,100,000,000 lire. Production increased until 1927, since which time it has remained practically stationary. Manufacturers however, have continued to improve their plants and processes and Italia cements are equal to the best foreign products, including special early hardening cements. The Federazione Nazionale Fascista del Cemento and the Societa' Incremento Applicazioni Cemento are recently formed organizations to encourage improvement in manufacture and to promote use of cement.—C. G. CLAIR AND M. N. CLAIR

Rotary kiln calculations. HANS BUSSMEYER. *Zement* (Germany), May, 1930, V. 19, No. 22, p. 522-4.—Author criticizes article by A. B. Helbig and contests his statement that normal rotary kiln with waste heat recovery is superior to "Lepol"-kiln manufactured by Polysius, Dessau (Germany). Several calculations of Helbig are corrected and tables recalculated. It is claimed that the "Lepol"-kiln has several advantages over any other rotary kiln. Heat calculations for both kinds are given and heat economy of "Lepol"-kiln is especially characterized. (c. f. A. B. Helbig, *Zement* (Germany), May, 1930, V. 19, No. 19, p. 440-4.)—A. E. BEITLICH

Use and abuse of building materials. Cement. A. M. GILES. *Builder* (England), May 2, 1930, V. 138, No. 4552, p. 870; No. 4553, p. 928; No. 4554, p. 969; No. 4556, p. 1013.—Article opens with brief history of development of cement manufacture and its composition. Cement contains 60-65 per cent lime, 20-25 per cent silica, 6-10 per cent alumina, small percentage of oxides of iron, and smaller percentages of other impurities. In setting, it is assumed that silicate of lime breaks down from 3 $CaO.Si\ O_2$ to a compound having one molecule of lime, the other molecules combining with water to form hydrate of lime. Setting time may be delayed by combination of sulphur anhydride or SO_3 with lime to form lime sulphate. Therefore the percentage of sulphur anhydride should not exceed 2.75 per cent. Ratio of lime (after amount to satisfy sulphur anhydride has been deducted) to sum of silica and alumina content should not be greater than 2.9 or less than 2. Manufacture. Main points of interest after excavation of raw material are crushing and grinding, and in wet process, final adjustments as to composition of slurry. Slurry passes down rotary kilns and its temperature rises to 3000° F, causing it to be first dried and then calcined. Resulting clinker is ground to finished cement. Samples for test are required by British Standard Specification to be taken from quantities of not more than 250 tons. The main tests required are for fineness of grinding, setting time, chemical composition, tensile strength of neat cement, and of mixture of cement and sand, and finally soundness. In addition to usual tests for setting time, rough method suggested by Dr. Faber in the Concrete Year Book is described. A 3-in. square pat, 1 in. thick should be placed on a piece of iron, slate or glass. Its progress of setting should be observed and in 18 to 24 hrs. it should have hardened sufficiently to resist any

impression by thumb-nail, while in 48 hours it should not be easy to break pat with fingers. Although there is considerable decrease in volume when dry ingredients of concrete are mixed with water, when concrete has set there is expansion which may not show for several years. Soundness test gives a measure of effect of this post-setting expansion. Expansion comparable with that resulting from long period may be obtained in a few hours by placing the cement in boiling water. The sample should be aerated by being spread out in a layer not more than 3 in. thick and left for 24 hours in a temperature of 58 to 64° F. The hardness test is well known as the "Le Chatier" test. A simpler method consists of placing a 3-in. diameter pat on a 4-in. sq. plate of glass. This is kept in moist atmosphere for 24 hours and then placed an inch above boiling water for about 5 hours. After cooling it can be removed from the glass, and should have retained its lens shape and give a clear sounding ring when struck with knuckle or lead pencil. Cement with high alumina content is quick setting and although, on account of its composition it does not conform to the standard specification, its strength is quite up to standard. Much heat is evolved during setting—an advantage in frosty weather—but it should be kept wet in order to make up for the water lost by evaporation. Care must be taken to avoid contamination by lime or ordinary portland cement. For white cement, iron oxide must be absent.—JOHN E. ADAMS

Hardening of Sorel cements. A. KRIEGER. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 36, p. 577-8.—The compound, $2MgO.MgCl_2.9H_2O$ is always present, but other substances in a gel form are also there for ratio of $MgCl_2$:$Mg(OH_2)$ may vary from 1:3 to 1:15. It is suggested, however, that initial hardening is due to this compound. Strength seems to depend upon the water-cement ratio.—F. O. ANDEREGG

Gaize cement for sea work. G. BAIRE. *Rev. materiaux construction trav. publics* (France), 1930, No. 248, p. 168-70.—Gaize is a siliceous material of sedimentary origin which is about ⅓ soluble in 20 per cent KOH after 20 hours of cold contact and 4 at 50 to 65° C. Exposure to sea water seems to increase the amount of active silica. A good cement is obtained on grinding one part of gaize with two of portland cement clinker plus a trace of gypsum. Its use was interrupted by the war, but certain experimental installations in sea water in 1910-11 have stood up so well that its use in sea water has been revived.—F. O. ANDEREGG

Blast furnace cements. A. O. PURDON. *Rev. materiaux construction trav. publics* (France), 1930, No. 249, p. 205-12.—Blast furnace cements, made by grinding portland cement clinker with blast furnace slags of proper composition, are giving very good results. Early strengths are lower than those of portland cement but improve later. Volume change is small; resistance to salt solutions is good; while danger from sulfur in slag is regarded as negligible.—F. O. ANDEREGG

Researches on action of inhibitors of setting of cements. *Rev. materiaux construction trav. publics* (France), Feb., 1930, No. 245, p. 50.—Berger gives following conclusions from researches carried out with 4 samples of anhydrite, one sample of gypsum, one of plaster and cement clinkers. To obtain cement which sets normally with anhydrite, it is necessary to use more SO_3 than with gypsum or plaster of Paris. The plasticity of cement which contains anhydrite is less than that of a cement in which gypsum is used. The fineness of the anhydrite has considerable importance with regard to plasticity of cement, but various qualities of natural anhydrite do not present any distinctive features. It is preferable to crush slow setting component separately from clinker. Quantity of SO_3 existing in solution of "inhibited" cement is

proportionate to solubility of inhibitor used. This aspect of subject deserves further study as results obtained so far are not final.—A. SIZE

Dosage of soluble silica in pozzuolanic cements. BAIRE. *Revue materiaux construction trav. publics* (France), Feb., 1930, No. 245, p. 61-62.—Method indicated by Chesneau is only suitable for estimating soluble silica in unmixed cements; for pozzuolanic cements the results obtained are not satisfactory, any more than in regard to cements obtained by mixing pozzuolane with portland cement. Author recommends combining hydrochloric acid method and carbonate of soda method for mixed cements, as ensuring complete dissolution. The mixtures contain at the same time silicates and non-combined silica.—A. SIZE

Hydrates of tricalcium aluminate. WILHELM EITEL. *Zement* (Germany), April, 1930, V. 19, No. 17, p. 394-9.—Discussion of research work on calcium-aluminates in connection with work done by Th. Thorvaldson. Studies concerned the volume changes of test pieces in sulphate waters. Hydrates of the tricalcium-aluminate were examined and reactions with water studied. Four different hydrates could be identified and their optical properties determined. These are hydrates with 6, 8, 10½ and 12 molecules of water. The heat of solution of these compounds is cited. A great number of references are given.—A. E. BEITLICH

MISCELLANEOUS

Report on accident during application of protective coating on concrete. DR. RICHARD GRUN. *Zement* (Germany), April, 1930, V. 19, No. 16, p. 383-4.—A water tank with a capacity of 100 cu. meters was provided with a protective inner coating of a bituminous preparation. Evaporating solvents formed with air explosive mixtures which caused death of two laborers. Following precautions should be observed: coating material should not contain any substances with low boiling point; flash point should be determined, smoking and open lights must be prohibited during and after application of coating. Sufficient ventilation must be provided for in closed chambers and tanks.—A. E. BEITLICH

Contribution to knowledge of old mortars. KARL BIEHL. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 51, p. 839-41; No. 53, p. 877-8.—Samples of mortar from German buildings ranging from the 16th to 19th centuries have been studied. Most of them were quite fat. Trass was found in only one mortar and then in small amount. From Persia one mortar was of gypsum without sand, while one of later date was fat lime mortar containing ground brick, showing influence of Romans.—F. O. ANDEREGG

Magnesia cements. *La Revue Industrielle* (France, Feb., 1930; reviewed in *L'Industrie Chimique* (France), June, 1930, V. 17, No. 197, p. 406.—Most important magnesia cement is "Sorel"-cement, which consists of mixture of magnesium oxide and magnesium chloride. Variations in cement are due to composition of magnesium oxide, which is obtained by calcination of magnesite or magnesium carbonate. Good magnesite, which is used for very pure cements, is calcined at 500° C., while magnesites containing ferric oxides need a temperature of 800° C. Ignited material is mixed with different materials such as saw dust, asbestos fibres, sand, cork or diatomaceous earth. These mixtures so obtained are mixed with solution of magnesium chloride of 22° Be. Author describes also some other methods of manufacture of magnesia cements. A. E. BEITLICH

Refractory mortars. O. PHILIPP. *Chem. Fabrik* (Germany), 1930, p. 86; reviewed in *L'Industrie Chimique* (France), June, 1930, V. 17, No. 197, p. 405.—Refractory mortar, which is to be used for construction of firebrick linings, must have sufficient adhesive properties and should not have a higher porosity after exposure to fire than the bricks. First condition is fulfilled when fire clay is used with or without binder like sodium silicate or dextrin. Refractory mortars, which have to stand very high temperatures are mostly made from the brick material itself by grinding and mixing powder with suitable cement like bentonite. Instead of cement one can use mixture of starch solution and glass or quartz powder.—A. E. BEITLICH

Bauxite production in France. B. CHARRIN. *Le Ciment*, May, 1930, p. 190.—Bauxite deposits are located in Southern France. Of these the Var yielded about 520,000 tons in 1928 and the Hérault 110,000 tons. France leads in production of bauxite with an annual output of over 600,000 tons. United States production, highest in 1920, has dropped to 300,000 tons (5th place) due to inferior quality and higher cost of production. Fifty per cent of bauxite produced is utilized in aluminum industry; 30 per cent is consumed by alumina cements; the rest used in the chemical industries. The world's production of aluminum demands about 850,000 tons of bauxite a year. A conservative estimate of the bauxite still available for exploitation in France is as follows: Var with 8 million tons; Hérault with 5 million tons; Bouches-du-Rhone with 2 million tons and Ariege with one million tons. Half of the above deposits contain a maximum of 7 to 8 per cent silica, a limit acceptable in the manufacture of aluminum and alumina cement.—MRS. M. A. CORBIN

Chemical composition of bauxites. V. CHARRIN. *Génie Civil* (France), Jan. 18, 1930, V. 18, No. 3, p. 63-64.—Red bauxites which are very abundant in France, have just begun to find very wide application in connection with cement. Alumina cements require a mineral not surpassing 8 to 10 per cent of silica and containing 30 per cent of iron and a proportion of 50 per cent at least of alumina. France has most and best quality bauxites, but in view of the ever-increasing demand for them for making aluminium and alumina cements it would be necessary to regulate the industry, and to amend present laws with regard to quarrying (law of 1810).—A. SIZE

Hydration of calcined gypsum. W. C. HANSEN, *Ind. Eng. Chem.*, June, 1930, V. 22, No. 6, p. 611-613.—A study was made to supply satisfactory explanation of accelerating or retarding action of soluble substances upon setting of gypsum-water pastes. Time-temperature curves obtained with calcined gypsum in various salt solutions indicated that controlling factor in setting is rate at which precipitation of gypsum takes place from its supersaturated solution. This theory was corroborated by demonstrating that foreign salts have a marked effect upon rate of gypsum precipitation from mixed solutions of calcium nitrate and ammonium sulfate. It is possible that effects of foreign substances on setting of portland cement also may be explained by their effects upon rate of precipitation.—ROY N. YOUNG

PROPERTIES OF CONCRETE

Trouble of concrete. *Australasian Eng.*, May 7, 1930, V. 30, No. 167, p. 20.—Contraction of air hardened concrete is about three times greater than that of concrete hardened under water. Sulphur in aggregate may also cause excessive expansion. An example is given of 3-in. concrete floor which pushed a wall over 2 in. in six months. Excessive heat may cause disintegration; a concrete foundation to a furnace, separated from the actual fire by 2 courses of 9 in. brickwork could, after a time, be broken away with the fingers. Broken firebrick aggregates are satisfactory if ample time is allowed for maturing and hardening delayed by placing wet bags over concrete. Finishing surfaces of

floors should be placed while under layer is still green, or there will not be proper cohesion between the two layers.—JOHN E. ADAMS

New comparisons between tensile, flexural and compressive strengths. R. FERET. *Rev. materiaux construction trav. publics* (France), 1930, No. 244, p. 1-4; No. 245, p. 52-60; No. 246, p. 83-95; No. 247, p. 127-33. —Search of literature has brought to light several comparisons of tensile, flexural and compressive strengths. Results are plotted and in general it is found that first two properties are proportional to each other and to the $\frac{2}{3}$ power of compressive strengths. Some exceptions exist, however. On plotting the ratio between the flexural and compressive strengths against water-cement ratio a number of straight lines were found. In general, alumina cements have lowest tensile-compressive ratios, followed by the portland cements which set lime free, and then the pozzuolanic cements. With moist storages and within certain limits of aggregate compositions, the water-cement ratio is found to be most important in controlling the strengths. On storing in corrosive waters, like $MgSO_4$, results vary with nature of cement.—F. O. ANDEREGG

The impermeability of concrete to water. C. R. PLATZMANN. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 40, p. 676-7; No. 43, p. 718-20; No. 45, p. 748-9.—After review of literature, importance of grading of aggregate is pointed out. Various methods of surface hardening and surface protective coatings are discussed.—F. O. ANDEREGG

Use of concrete and reinforced concrete on the railways. M. F. B. FREEMAN AND M. E. KRICK. *Génie Civil* (France), Feb. 8, 1930, V. 96, No. 6, p. 144.—Concrete and reinforced concrete are widely used for various railway undertakings owing to low cost of upkeep and their refractory character. But it is necessary to keep a close watch on changes caused by time, etc., and to take precautions in regard to calculation of weights to be supported by bridges. Smoke of locomotives has no deleterious influence on concrete provided surface is smooth and has no fissures. Iron and steel bars must be sufficiently far from surface of concrete to avoid attack by rust.—A. SIZE

Theory of the expansion of liquid cements. HENRI LAFUMA, *Rev. Mat. Constr.*, Jan., 1930, No. 244, p. 4-8.—Swelling of quick lime by slaking is due to the spontaneous pulverization of the lime and increase of absolute volume of solid phases during reaction. Apparent volume is enormously increased by this process. It is necessary, in order to improve mortars, to eliminate these reactions by dissolving solid salts beforehand. Author studies successively chemical disaggregation of aluminous and hyper-aluminous portland cements; setting of tempering cements; swelling action which is exercised on mortar by presence of aluminium plates, and the expansion of quick setting mortars. —A. SIZE

Concrete; effect of aggressive liquids on concrete and possibilities of concrete protection. M. GRUEN. *Chimie et Industrie* (France), Jan., 1930; reviewed in *L'Industrie Chimique* (France), June 1930, V. 17, No. 197, p. 406.—In general all acids attack concrete. This effect increases with concentration of acid. Gaseous acids too have corrosive properties. Certain salts are able to attack concrete. Sulphates have the tendency to form calcium-sulphoaluminates. Fatty substances corrode concrete. In order to prevent concrete attacks, one can use suitable mixtures, or protect surface with coatings. Grain size of sand plays important role. Coating may be either bitumen, tar or some varnish.—A. E. BEITLICH

Contribution to valuation of certain mixed storage of cement test pieces for practice. H. BURCHARTZ. *Zement* (Germany), May, 1930, V. 19, No. 21 and 22, p. 488-92, 510-5.—Investigations were made of variations in strength of test pieces under different storage conditions. Five different kinds of cement: one high-early strength cement, one portland cement burned in rotary kiln, one portland cement burned in shaft kiln, one iron-portland cement and one blast furnace cement were studied. Normal strength tests were made

under varying storage conditions, and gain or loss of water during storage was determined from each test piece. Strength of test pieces which are stored in water after preceding normal storage decreases in general. Tensile strength is more effected than compressive strength, especially during short water storage. —A. E. BEITLICH

Effects on concrete. "Einfluesse auf Beton." A. KLEINLOGEL, F. HUNDESHAGEN AND OTTO GRAF. 3rd edition, 1930, Wilhelm Ernst & Sohn, Berlin (Germany), R. M. 39.50; reviewed in *Zement* (Germany), May, 1930, V. 19, No. 19, p. 456.—Book illustrates possibilities of corrosion of concrete, danger and damage through chemical agents, aggressive waters and other unfavorable conditions and shows ways to prevent such damage by proper precautions. Many references are given.—A. E. BEITLICH

Building protection. "Der Bautenschutz." (New journal) Wilhelm Ernst & Sohn, Berlin (Germany); reviewed in *Zement* (Germany), May, 1930, V. 19, No. 18, p. 432.—Journal appears together with *Beton und Eisen* (Germany), and brings articles concerning new tests, investigations and experiences in the field of concrete and effect of water, weather and fire on concrete.—A. E. BEITLICH

Equipment for testing the water impermeability of concrete. HANS HECHT. *Zement* (Germany), May, 1930, V. 19, No. 20, p. 472-3.—Author describes apparatus similar to one designed by Otzen. Water pressure is kept constant by means of compressed air tank which is connected with large water reservoir. Twelve test pieces can be exposed simultaneously to different pressures. Apparatus can also be used for tests with aggressive waters and solutions and is entirely independent of any stationary water line. Test pieces up to 30 cm. in diameter can be tested. Pressure can be varied up to 20 atm.—A. E. BEITLICH

Concrete and reinforced concrete in fires. New experiences. A. WEISS. *Zement* (Germany), May, 1930, V. 19, No. 18, p. 424-7.—Behavior of concrete walls and ceilings during recent fires showed again superiority of concrete for fire resistance. Casings of iron columns should not be thinner than 10 cm.—A. E. BEITLICH

Control practice in reinforced concrete construction in erection of warehouse No. VII in Free Port of Stettin. (See FIELD CONSTRUCTION - Buildings.)

Blast furnace cements. (See MATERIALS—Cement.)

ENGINEERING DESIGN

Welded trusses developed for bridge floor reinforcing. H. M. BRINGHURST. *Eng. New Record*, July 3, 1930, V. 105, No. 1, p. 8.—Roadway slab reinforcing used on the new bridge over the Ohio River at Louisville, Ky., and on the Ambassador Bridge at Detroit is interesting example of truss-type reinforcement, and represents first use of arc welded material on bridges of this size. Reinforcing units are light trusses of Warren type made up of round bars. Web is formed by a continuous bar bent to a zig-zag shape and welded at bends to top and bottom chords, each of which consists of two straight round bars. Bars from which trusses are fabricated are furnished by mill in coils and are straightened at plant in straightening machines to remove mill scale. Webs are bent on compressed air machine and are spliced to facilitate handling. The bars are then assembled in a jig and each joint is electrically arc welded by hand. Special care is taken to avoid distortion from application of heat. After removal, each joint is tested with a pinch bar. At irregular intervals, trusses are tested to destruction as additional check. Specimens of long span fail from buckling of the top chord and those of short span fail by buckling of the web. Weld failures were not obtained in any tests.—D. E. LARSON

Design of road bridges. C. S. CHETTOE. *Roads and Rd. Constr.* (England), May 1, 1930, V. 8, No. 89, p. 149.—Rigid Frames. This article continues with discussion of rigid frames of semi-elliptical and parabolic type of arch frames which meet their abutment slabs at an almost vertical angle. They are more economical in material than true rigid rectangular frames and have better appearance. Attention is drawn to difference between active pressure and passive pressure exerted by earth in case of retaining walls, the latter being, when maximum, much greater than former. According to Rankine, maximum passive horizontal pressure bears same ratio to downward pressure at any point, as downward pressure bears to active horizontal pressure. Although assumption that pressure is horizontal may hold when walls are constructed in timbered trench against vertical surface of consolidated earth, it is not true when filling is piled behind wall. In general, it is sufficient to design for active pressure. Passive pressure on frame sides reduced crown stress but will increase moments at corners. For very flexible frames it may be advisable to allow for some passive pressure. In culvert design, the more flexible the culvert the less weight of earth carried by it. Conditions will be more favorable if culvert is excavated out of existing ground up to haunches. Increased side pressure due to steep sides to a ravine has occasionally caused failure of culverts constructed in it. Filling should be brought up equally on both sides, otherwise allowance must be made in design. Reference is made to Kleinlögel's book for cases of side loadings.—JOHN E. ADAMS

A new department store in Frankfurt a. M. (Germany). RUDOLF KLAR. *Zement* (Germany), May, 1930, V. 19, No. 18, p. 431-2.—Building is located in business center and limited space was available for transportation and storage of construction materials. Foundations were placed on bad underground which allowed only 2 kg./cm.^{2} pressure. High early strength cement was used. Skeleton structure shows beams with span of 8 meters. A total of 8500 m^2 ceilings were placed. Ceiling of basement is reinforced concrete, one over first floor is crosswise reinforced Remy ceiling, rest are ordinary reinforced Remy ceilings. Cross sections of beams were made as small as possible for architectonical reasons and their reinforcements were made especially strong. Concrete test pieces gave 280 kg./cm^2. compressive strength after 12 days.—A. E. BEITLICH

Specifications of the German committee for reinforced concrete of September, 1925. "Bestimmungen des deutschen Ausschusses fuer Eisenbetom vom September 1925." 5. edition, 1930, Wilhelm Ernst & Sohn, Berlin (Germany), R. M. 1.80. Reviewed in *Zement* (Germany), May, 1930, V. 19, No. 20, p. 480.—Four parts deal with following subjects: specifications for reinforced concrete, concrete ceilings, concrete buildings and cube tests.—A. E. BEITLICH

Modern skeleton building in Kiel (Germany). WENZEL. *Zement* (Germany), April, 1930, V. 19, No. 16, p. 378-9.—Building is 112 m. long and is made without any shrinkage joints. Concrete was kept wet for 6 weeks by means of special sprinkler system and no visible shrinkage cracks could be observed after one year. Floor slabs, which have solid rib in center, have span of 6 m. and are 1.30 m. wide. They rest on 20 x 40 cm. concrete columns. Main floor consists of 14 cm. thick concrete slabs which are supported by 23 cm. thick continuous brick wall.—A. E. BEITLICH

The convention hall in Memmingen (Germany). WECHS. *Zement* (Germany), May, 1930, V. 19, No. 22, p. 521-2.—Description of construction of large hall in reinforced concrete. Building is 66 m. long, 26.50 m. wide and 12.50 m. high. Concrete columns have cross-shaped cross-section; they are 12 m. high and 1.05 and 1.50 m. wide. Side walls are solid and 25 cm. thick.—A. E. BEITLICH

Project of the dam of Tecamachalco. ADOLFO ORIVE ALBA. *Ingenieria* (Mexico), Feb., 1930, p. 60-61.—Results of an investigation made for Secretary of Communications to determine the location and design of dam to control Los Morales river are given. A survey was made to determine the underground conditions. A cross section of the site is given showing geological formation. The conglomeration clay formation near surface in some parts is said to be similar to that under right side of the St. Francis dam, which recently failed; so special precautions were considered necessary. Rubble or rock-fill type of dam was considered most adaptable to the conditions; but not enough materials were available; so gravity and arch-gravity dams of concrete were investigated. It was decided to build a gravity dam, designed assuming a pressure on the base varying from full head of water at upstream face and into line of vertical drains to zero at downstream face. The result of all forces was made to fall within middle third for both empty and full conditions. The coefficient of sliding was kept less than 0.70. A sketch of proposed cross section is given, which shows all important details. Section is of typical gravity kind of cyclopean concrete, four meters wide at top, 16 meters wide at the base, and 23 meters high. There is a series of vertical drains 10 centimeters in diameter spaced at two-meter intervals parallel to upstream face, and two meters from it. Drains are intercepted by an inspection and drainage gallery. Cut-off walls extend below the base of dam both at upstream and downstream sides. Purpose of permeable downstream toe being to prevent the movement of material if it becomes softened by the flow of water. A spillway opening is provided to take care of both the San Joaquin and the Tecamachalco excess flows. An emergency conduit 0.75 meters in diameter provides for emergency flows.—MILES N. CLAIR AND C. G. CLAIR

Design and economy of plain and reinforced concrete dams. E. PROBST AND F. TOLKE. *Zeitschrift Ver. deu. Ing.* (Germany), 1930, V. 74, Nos. 13 and 15.—Paper, presented at Second International Power Conference at Berlin, is brief review of various types of dams and problems encountered in their use. Dam cost is such large part of total cost of a hydroelectric project (29, 29 and 40% for three cases cited) that selection of most economical structure is important. Arched gravity dam is not recommended unless joints are to be grouted. Grouting is advised in spring when masonry is at its lowest temperature. Danger of uplift should not be underestimated. Drainage system will relieve uplift and may be considered as an additional precaution. It should not be considered in design, however, as its continued functioning throughout long life of dam is not certain. Rather arbitrary assumptions of gravity dam proportions are justifiable when uncertainty of stresses near base and force of uplift are considered. Base to height ratios used in recent practice (ten dams listed) indicate that while about 0.70 is used in United States and in Germany, more conservative values (up to 0.97) are common in other European countries. Larger section is not necessarily safer section, because of cracks from higher "secondary" stresses and from shrinkage. Wherever possible arch dam should be used rather than gravity dam. Some American and European types of slab and buttress dams are discussed from viewpoint of cost and durability. These types, compared to gravity and arch dams have advantage of clearly understood structural action. Thin reinforced sections, however, face possibility of corrosion of steel. Condition of foundation rock is of primary importance to safety of structure and should be thoroughly investigated. Proper care is not always used to obtain concrete that resists soakage and frost action. These properties may sometimes be more important than a high compressive strength. Large model tests and observations on existing structures are recommended for increasing knowledge of dam construction. Formation of an international bureau of records on dams is desirable.—A. A. BRIELMAIER

Concrete and reinforced concrete for water structures. F. HIRT. *Zement* (Germany), May, 1930, V. 19, No. 20, p. 478-80.—Draining of large district in German lowlands and necessary concrete structures are described. Total area to be drained was 40 million square meters. Deepest part lies 1.43 m. under sea level. It was necessary to move 500,000 cu. meters ground. Channel was dug 15 m. wide at top and 10 m. at bottom, with fall of 1 cm. per 100 m. Highway bridge of reinforced concrete was built over channel. In order to lead water underneath a second channel a sewer was built of reinforced concrete. Sewer has three openings of 10 m^2 each. Total length is 31.50 m. Underground was soft sand. Third outstanding structure is pumping station near Borssum. Each of three rotary pumps delivers 8 cu. meters water per second and each is driven by two motors, one with 340 H. P. for pumping up to 2 m. and one with 600 H. P. for pumping from 2 to 6 m. Building rests on 400 wooden piles, each having diameter of 28 to 30 cm. Floor of building is made of reinforced concrete. Blast furnace cement was used for all constructions.—A. E. BEITLICH

The necessary reinforcements for reinforced concrete girder slabs. KURT BERNHARD. *Zement* (Germany), April, 1930, V. 19, No. 16, 17, 19 and 20, p. 379-83, 405-9, 447-52 and 474-8.—Formulas and equations are given for calculation of necessary reinforcements for girder slabs. Steel coefficient can be calculated and amount of steel determined for slabs of any cross section. All stresses are analyzed. Examples show calculations for single slabs and slab ceilings. Special consideration is given to different fields, end and center fields, with varying number of supports.—A. E. BEITLICH

Simplified calculations of flexible slabs. "Die vereinfachte Berechnung biegsamer Platten." MARCUS. 2nd edition. Julius Springer, Berlin, 1929, R. M. 11.00. Reviewed in *Zement* (Germany), April, 1930, V. 19, No. 17, p. 410.—Book gives calculations and describes stresses in all kinds of slabs and ceilings, and examples show that simplified formulas are well suited to the calculation of such work.—A. E. BEITLICH

Moments in continuous slabs and their reinforcements. SCHNEEMANN. *Zement* (Germany), May, 1930, V. 19, No. 21, p. 497-9.—Calculations are given, which show different moments in continuous slabs. Necessary change of standard specifications which increases support moments and reinforcements is suggested.—A. E. BEITLICH

Reinforced concrete ties after system Emperger. *Zement* (Germany), May, 1930, V. 19, No. 21, p. 499-502.—Weight of wooden ties is in general 75 kg., while concrete ties weigh 150 kg. This greater weight is more suitable to stand high vibrations. A special type of concrete ties is described, which consists of three parts. Transportation and placing of these ties is easier than ties consisting of one piece only. Reinforcements provide flexible connections of three parts. Iron parts are protected against rust by coatings or special arrangements. Drawings and photographs show all details, and practical experiences are given.—A. E. BEITLICH

Nomogram for determining the area of longitudinal steel. JORGE QUIJANO. *Ingenieria* (Mexico), Jan., 1930, p. 37.—A simple alignment or nomographic chart, one of a series of such charts for use in reinforced concrete design, solving the relation $A_s = pA_c$. Left hand scale or line Ac, middle scale As, and right scale p. All in metric units. Explanation of use is given on full page chart.—MILES N. CLAIR AND C. G. CLAIR

Nomogram for calculating bond stress. JORGE QUIJANO. *Ingenieria* (Mexico), Jan., 1930, p. 30-31.—A simple alignment or nomographic chart, one of a series of such charts for use in reinforced concrete design, solving the relation $uEo = Vb$. Left hand scale of line $\frac{u}{V}$, middle scale $\frac{As}{b}$ and right scale

diameter of bars. Explanation and examples of scale are given for determining various factors. All in metric units.—MILES N. CLAIR AND C. G. CLAIR

High unit stresses recommended for concrete-cased I-beams. *Eng. New Record*, May 15, 1930, V. 104, No. 20, p. 798-799.—A recommendation for 24,000 lb. unit stress in steel I-beams of floor framing when cased in reinforced concrete and covered with slab of same material is main conclusion of report presented on May 12 to Western Society of Engineers by committee which, in co-operation with Chicago building department, has conducted tests on floor construction of this type. Recommendation applies to I-beams up to 24 in. in depth when wrapped in steel wire fabric or mesh and incased in rectangle of concrete with minimum covering of 2 in. on flanges of I-beam and when used in connection with concrete floor slab not less than 2½ in. thick above top of flange of I-beam. Committee presented following facts based on study of number of tests: (1) Concrete and structural steel act together to form composite beam. (2) Influence of concrete prevails under vibration and impact. (3) Observed stresses in steel and deflections in slab are far below those computed on assumption that entire load is taken by steel alone. (4) Considerable economy in support of live loads may be obtained by utilizing joint action of concrete and steel. (5) Within practical limits composite beam conforms to theory and may be designed by methods analogous to those used in case of reinforced concrete T-beam. (6) Added strength of concrete may be taken advantage of in design by simple method of adopting higher unit working stresses in steel and then, with these stresses, calculating steel alone.—D. E. LARSON

Layout and construction of a new wet-process cement plant in Texas. TERRELL BARTLETT. *Eng. News Record*, May 29, 1930. V. 104, No. 22, p. 889-893.—Structural and manufacturing features of recently completed wet-process cement mill near San Antonio, Texas, for Republic Portland Cement Co., involve the following factors of interest: site selection; easily available quarry material in one place; layout of plant to reduce costs to a minimum; use of an unusual amount of concrete in the structures; concrete craneway frame; foundations on both rock and clay; large grinding capacity; close control, and silo construction for stock house. Because of the nature of the industry use of concrete was considered to be good policy wherever its cost would be equal to or less than steel. Steel is costly in Texas because of freight charges and concrete is cheap on account of labor conditions. The concrete craneway is unusual structural feature. In designing beams at the top it was necessary to consider impact of loaded crane weighing 50 tons and transverse thrust resulting from movement of crane trolley. In designing for wind load, each side frame was made laterally self supporting by use of buttress shaped columns on spread footings resting on rock. Columns of each frame are connected at mid-height by row of double-corbelled concrete struts. Analysis indicated that expansion joint was necessary in 300-ft. frame length to prevent undue temperature stresses in end columns.—D. E. LARSON

Curves for analysis of rectangular continuous beams with axes semi-circular in plan. ST. HESSLER. *Beton u. Eisen* (Germany), April 20, 1930, V. 29, Heft 8, p. 149.—Moment curves are given for torsion and direct bending in uniformly loaded beams, continuous over two, three, and four equal spans, for both fixed and hinged condition of end supports. Reference is made to article by author (cf. *Beton u. Eisen*, Heft 23, 1927) for treatment of theoretical basis of curves.—A. A. BRIELMAIER

Model tests of a flat-slab crossing structure. A. BUHLER. *Beton u. Eisen* (Germany), April 20, 1930, V. 29, Heft 8, p. 154.—This is brief summary of some tests made by Swiss Federal Railways. Model consisted of two spans with an overall length of 40 ft., width of 7½ ft. and height of 10 ft. Intermediate support was column with flared head and end supports were vertical

thin slabs with knee strengthened by bracket similar to part of center column head. Structure was loaded to failure with lead billets, and comprehensive set of observations made on several phases of structural behaviour. Among the conclusions the following points are mentioned: Cracks can not be prevented but may be kept small by proper distribution of steel. For usual steel ratios and concrete of fair quality ultimate load is dependent on yield point of steel. Shrinkage in concrete should be considered as about 0.05 per cent (Swiss Reinforced Concrete Standards call for 0.025 per cent). Use of reinforcement with high elastic limit is definite advance in concrete construction. Steel used in test showed elastic limit of from 57,000 to 77,000 lbs. per sq. in. From construction viewpoint flat-slab model was not very satisfactory. Knees at end supports were subjected to irregular stresses and early cracking. Exact placing of steel was difficult. E value for concrete showed a variation of ± 20 per cent, and decreased with increase in loading. It increased by about 6 per cent between ages of 1 and 3 months. Plane sections do not remain planar in highly stressed regions. Permanent deflections became evident at loads equal to two or three times design loads. Test cubes showed considerable variation in strength. Compressive and flexural tests of prisms showed permanent deformations at low stresses for young concrete. Possibility of permanent deformation as well as strength should be considered in determining time limits for removing forms.—A. A. BRIELMAIER

Successful reinforced concrete base for street railway tracks. I. O. MALL. *Concrete*, April, 1930, V. 36, No. 4, p. 13.—Methods followed in development of reinforced concrete track support in Canal Street, New Orleans, is combination of careful structural design supported by thorough tests under conditions simulating actual service. Roadbed structure consists primarily of reinforced concrete foundation to which rails are anchored by means of resilient rail anchorages. Foundation slab is shaped to form continuous girder beneath each rail and parallel to rail. The reinforcement in each of these girders consists of two $\frac{5}{8}$ in. straight and deformed bars. The transverse reinforcement, extending the full width of slab and passing under each rail, is also of $\frac{5}{8}$ in. round deformed bars. Two continuous longitudinal angles are embedded in concrete beneath and parallel to each rail. Rail anchorage units are fastened to these angles, which are held in parallel alignment by deformed straps welded to angles at points of contact. Tie rods, which extend from rail to rail, are covered with an asphaltic material to prevent their bonding to concrete. The cushion between rail and pavement along its side is accomplished by application of $\frac{1}{4}$ in. coat of asphalt to rail before concrete is placed. Transmission of shock from rail to concrete base is prevented by placing $\frac{1}{4}$ in. thickness of elastite immediately under base of rail, this strip being held in place by special wire clips. Further elimination of impact is obtained by means of a specially designed anchor plate or diaphragm.—C. BACHMANN

Concerning concrete and cement. R. E. *Roads and Rd. Constr.* (England), June 2, 1930, V. 8, No. 90, p. 196.—Referring to various Building Science Abstracts, the author stresses need for taking into account contraction stresses in reinforced concrete structures. Contraction per unit length varies from .0002 at three months to .0005 after six years, when setting stress will be 128 lb. per sq. in. For piles in water bearing soil, permissible load in tons is given by $P = Wh/(S + 1)$ where W is the weight of monkey in tons, h the fall in ft., and S the average penetration in inches for the last five blows. For power rams $P = Wh/(S + 0.1)$. Additional supporting power may be obtained by fitting to head of pile a 5 ft. square slab collar. Regarding cement guns, it is found that allowance for bulking should be made. If 1 to 3 dry sand mix is specified, 6 per cent moisture in pit run sand increases the bulk by 33 per cent and cement ratio will become 1 to $2\frac{1}{4}$ instead of 1 to 3. Furthermore it is found that when mix is applied to hard surfaces, 25 per cent of sand is lost through rebounding due to its velocity. Ratio of placed mix, then be-

comes 1 to 1.68. For coloring concrete, organic pigments should be avoided in favor of inorganic pigments such as ochres, umbers and oxides of iron, and synthetic colors like ultramarine. These, which should be finely ground as cement, do not decrease the strength.—John E. Adams

Architectural Design

Concrete architecture. Willi Lutz. *Zement* (Germany), May, 1930, V. 19, No. 19, p. 445-7.—Concrete in hands of an artist has many advantages over natural building materials. It has highest plasticity and durability and can be placed without joints. Molds can be used many times. No material waste. Selection of aggregates and admixtures allows variations of color and texture according to its purpose. Application of concrete in artistic architecture is illustrated on several reconstructions of big warehouse showing its use for facing of stairways and outside structures.—A. E. Beitlich

Concrete beautiful. Ernest O. Bostrom. *Western Architect*, May, 1930, p. 72-73.—An architect's appreciation of concrete as an architectural medium combining strength with form and color.—Rexford Newcomb

New concrete plastics. Dahl. *Zement* (Germany), June, 1930, V. 19, No. 23, p. 540-1.—Modern building construction uses more and more methods to provide outside of buildings with decorative finish and ornamental plastics from the hands of an artist. A number of photographs show what can be done along this line. Mtehods are described and suggestions for their application are given.—A. E. Beitlich

Construction and shaping of skyscrapers of reinforced concrete. (See Field Construction—Buildings.)

Field Construction

Bridges

Erection of caisson of Poughkeepsie suspension bridge. H. G. Schwegler. *Der Bauingenieur* (Germany), Jan., 1930, V. 11, No. 5, p. 71-2.—Highway bridge over Hudson river is 900 m. long with suspended portion of 450 m. Two main towers rest on 19.8 m. high concrete piers which are placed on concrete caissons. Dimensions of caissons are: 40.8 m. long, 18 m. wide and 31.2 m. high. Difficulties were encountered in placing one caisson. Upper part leaned over during construction under angle of 43 degrees. Erection of caisson which weighs 11,000 tons is described.—A. E. Beitlich

Thin bridge floors concreted in Vermont winter. H. L. Tilton and F. B. Saunders. *Eng. News-Record*, June 19, 1930, V. 104, No. 25, p. 1002-1005.—In winter of 1928 Vermont department of highways was confronted with task of completing large number of 1200 bridges which were destroyed by great flood of 1927. Completion of these bridges was necessary to relieve temporary structures which would be swept away with breaking up of ice. Concrete work consisted mainly of piers, abutments and floor slabs and was made difficult by temperatures as low as —20° F. In placing concrete in piers and abutments a 2 per cent solution of calcium chloride was incorporated in 1:2½:5 mix. Materials were heated by steam, furnished in one case by steam shovel previously used for excavation. Steam jet was used in water tank and steam pipe grid under sand and stone piles. Kerosene flame heater was used in mixer. Heating operations were started 24 hours before concreting. By these methods concrete was discharged from the mixer at temperature of 75° or higher. Freshly placed concrete was protected by canvas placed over top and down sides with outlets for live steam between canvas and forms. A

temperature of 50° was maintained even in severe weather. Heat was removed after 48 hours and as late as ten days after placing, the surface of concrete was still warm when forms were removed. Floor slabs of 1:2:4 concrete 5 in. to 9 in. thick were required by specifications to be inclosed and heated for 14 days, but to expedite opening of bridges and to decrease cost of heating, high-early-strength cement was used. Materials were heated as described above. Floor slabs were protected by canvas inclosure below. Heat was supplied by coke-burning salamanders and was confined entirely to canvas inclosure. About 125 sq. ft. of floor area was allowed per salamander with extra salamanders near the walls on windy days. Use of live steam instead of salamanders was soon abandoned. As soon as the concrete was screeded and broomed, building paper was laid on it. Then a covering of hay was spread on the paper and battened down with boards. By applying the paper directly to the concrete surface heat was retained uniformly in concrete. During first 24 hours temperature beneath paper on top of slab was from 2° to 3° higher than that in heated inclosure underneath slab. Test beams 6 in. x 6 in. x 36 in. were made from concrete in slab. These were laid on the slab and cured under identical conditions. Heating was stopped 24 hours after test beams developed a compressive strength of 2000 lb. per sq. in. This strength developed in 48 to 72 hours. Due to variable moisture content of aggregate, smallest amount of water to produce workable mix was specified. The cost of winter protection varied from 10 to 15 per cent depending on the size and location of the work.—ROBERT W. ABBETT

Subsiding bridge. *Roads Rd. Constr.* (England), June 2, 1930, V. 8, No. 90, p. 198.—Part of foundations to bridge over Salwarpe, Worchestershire were found to be undermined by scour of stream. Divers discovered earth and subsoil had been removed from under one abutment to depth of six feet for length of 16 ft. and 7 ft. back from face. Concrete in bags was inserted by divers, until whole cavity was filled, and adjacent part of river bed also made good with concrete in bags, and block stone.—JOHN E. ADAMS

Welded trusses developed for bridge floor. (See ENGINEERING DESIGN —Bridges.)

BUILDINGS

Construction and shaping of skyscrapers of reinforced concrete. "Konstruktion und Gestaltung grosser Geschossbauten in Eisenbeton." STORTZ. 1930, Konrad Wittwer, Stuttgart (Germany), R. M. 6.00. Reviewed in *Zement* (Germany), May, 1930, V. 19, No. 18, p. 432.—Details of skyscraper construction are discussed and suggestions are given for architectonical effects and their construction. Book is accompanied by many valuable illustrations.—A. E. BEITLICH

Construction of reinforced concrete tower for Navy Monument in Laboe near Kiel (Germany). WILHELM HAEVERNICK. *Der Bauingenieur* (Germany), Feb., 1930, V. 11, No. 7, p. 110-2.—Tower is 68.20 m. high, 13.80 m. wide and 31.50 m. long. Under ground consists of 5 m. thick layer of marl, then loam, 3 m. thick layer of sand and marl again. Structure rests on 1 m. thick cross reinforced concrete foundation. High quality iron portland cement and high alumina cement from Hochofenwerk Luebeck were used for construction of 10-story building. Concrete pump was used for delivery of 8 to 10 cu. meters of concrete per hour.—A. E. BEITLICH

Design and construction of the main building of the German Health Museum in Dresden (Germany). CURT G. SCHINKE. *Der Bauingenieur* (Germany), March, 1930, V. 11, No. 13, p. 229-32.—Main building which is 30 m. high is reinforced skeleton structure. Covered area is 43 m. by 50 m.

Building consists of two halls, one of them being 14.8 m. high, rooms for conventions, rooms for microscopical work, library and several rooms for lectures and exhibitions. Interesting feature is ceiling construction of big hall. Detailed description is given of formwork, concrete transportation, distribution and placing.—A. E. BEITLICH

A reinforced concrete skeleton structure in Breslau (Germany). OTTO VEIT. *Zement* (Germany), May, 1930, V. 19, No. 18, p. 429-30.—Bad underground conditions made foundation on concrete piles necessary on which reinforced concrete structure of 10-story building rests. A detailed description of the construction is given.—A. E. BEITLICH

German museum in Munich. L. HOFFMANN. *Zement* (Germany), May, 1930, V. 19, No. 20, p. 470-2.—Entire building project is divided into three parts. Building which contains collections and expositions was finished several years ago; buildings for library and conventions is under construction now. Latter structure has total length of 400 m. and has several large halls; one of them, which gives room for 2000 people, is 14 m. high. Many difficulties were encountered in placing foundations. It was necessary to make 520 small excavations which were filled with concrete on which steel structures of building rest. Reinforced concrete was used for most all of the superstructure. Ceilings with great spans were placed; roofs are covered with metal.—A. E. BEITLICH

Directions for construction of reinforced rib-ceilings with hollow bricks of pumice concrete. *Zement* (Germany), May, 1930, V. 19, No. 19, p. 455-6.—Great care must be taken for concrete forms. Bricks must be thoroughly wetted before being placed. It is necessary to provide for openings in the forms for pipes in order to prevent damage by later chiseling.—A. E. BEITLICH

The new construction of the building for the newspaper "Neue Mannheimer Zeitung" in Mannheim (Germany). NORKAUER. *Zement* (Germany), May, 1930, V. 19, No. 18, p. 427-9.—Building was erected in reinforced concrete skeleton construction. High early strength cement was used. Frost periods, which exposed structure to —28° C. for a long time, did no damage to building. Details illustrate the construction of foundations for heavy machinery.—A. E. BEITLICH

Concrete bricks for building construction. *Zement* (Germany), April, 1930, V. 19, No. 16, p. 384-5.—New form of concrete brick with porous core and hard outer shell is described. Mixture of one part of cement with ten parts of aggregates (gravel, slag, volcanic ash or pumice) are used for their manufacture. Form of bricks makes construction of any kind of wall possible. An empty air space is formed in interior of wall which provides good heat and sound insulation. Costs of construction can be reduced to about 50-60 per cent of the costs of ordinary brick masonry.—A. E. BEITLICH

New Storage warehouses of the Paris-Austerlitz station. CH. DANTIN. *Genie Civil* (France), Jan. 11, 1930, V. 96, p. 29-33.—To eliminate delays on a job comprising an area of 23,000 sq. m., great care was taken to provide satisfactory forms for all parts of the structure and to insure mechanical handling of materials. Rational choice of concrete proportions and careful supervision during hardening led to successful completion ahead of date set. Proportions were: 600 liters sand, 600 liters gravel and 350 kg. cement. To obtain a check on progress of hardening, samples were taken at the time of placing each member. These specimens were tested in flexure by means of a machine of lever type and removal of forms was postponed until strength values exceeded three times theoretically allowable limit. A table was posted giving safe stress and machine reading desired for each member.—MRS. M. A. CORBIN

Control practice in reinforced concrete construction in erection of warehouse No. VII in Free Port of Stettin (Germany). HERMANN

CANTZ. *Forscherarbeiten auf dem Gebiete des Eisenbetons* (Germany), 1930, V. 34, 71 pp.—Introduction deals with general tasks of construction control of concrete and reinforced concrete jobs. Example shows control work for construction of 5-story warehouse. Preliminary tests were made in laboratory erected in neighborhood of place of construction. Properties of cement and gravel, proportioning of mix and consistency were studied, especially from economical viewpoint. Sand which was used for construction contained up to four per cent loam. In order to find out if this has any unfavorable influence on concrete, tests were carried out with sand to which 12½ per cent of loam were mixed. No decrease in strength could be observed with this admixture. All construction materials were examined, and cement was used only when its 3-day strength was satisfactory. Sand was tested for its gradation, contents of loam and organic materials. Sodium hydroxide solution of 3 per cent was used for latter purpose. Investigations concerning consistency of mortar and concrete showed certain relations between necessary amount of cement and gradation (voids and surface) of aggregates. Method was developed to determine w/c ratio for any aggregates for a given consistency when amount of cement is given. Influence of low temperatures on compressive strength of mortars was studied. Even temperatures from 0° to +8° C. showed retarding effects. Formula was derived for calculation of 28-day strength of concrete for different mixes. Strength of concrete depends on strength of cement, w/c ratio and gradation of aggregates. Special consideration was given to influence of coarse aggregates and relation between cement and concrete strength. Quality of concrete was tested during construction by means of test cubes and beams. Construction control was also applied to mixing, working and finishing of concrete. Special equipment was made for exact measuring of construction materials. Detailed description is given of concrete distribution arrangement. Special care was taken in protecting concrete over night. All parts of building were tested after construction under heavy loads and deformations measured. Entire building occupies area of 47 x 218 m. Suggestions are given for erection of testing laboratories near the job. Thirty-five illustrations and twenty-three tables are given, and several references complete the article.—A. E. BEITLICH

How to save in concrete form work. A. B. MACMILLAN. *Concrete* April, 1930, V. 36, No. 4, p. 27.—Description of forms for girders, beams and floor slabs refers to what is ordinarily termed beam-and-girder construction. In general, following lumber sizes are used: (1) For beam and girder bottoms, 2-in. plank dressed down to 1¾ in. by the width of the beam. (2) For beam and girder sides, 1⅛ in. dressed. (3) For boards of floor form panels, ⅞ in. dressed. (4) For ledgers and ribbands, 1 x 6 in. nominal size, rough or dressed (5) For cleats (or battens) on beam and girder sides, 2 x 4 in. nominal size, rough or dressed. (6) For floor form joists, 2 x 6 in. to 2 x 10 in., depending on load and span. (7) For posts and heads of jack frame, 3 x 4 in. nominal size, rough or dressed. Girder forms are first to be set up. Both girder forms and beam forms are made in three parts, namely bottom plank and two sides. Ends of girder forms are supported by blocking up from uppermost column yoke, or on special framing of 2 x 4's fitted around opening in the column form. Sides of girder are notched out for beam. Girder sides should be cut 2 in. less than length of bottom plank. Girder sides and bottom are assembled separately Boards of sides are nailed to 2 x 4 battens or cleats and are set into place, and bottom plank is likewise set into place. Beam forms are handled similarly. Beam form ends are supported on 2 x 4's nailed to sides of girder forms at level of bottom of beam sides. Sides are 2 in. less in length than the bottom plank and 1 in. shortage at each end is again filled in by beveled 2 x 4's nailed against girder sides with double-headed nails.—C. BACHMANN

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, May, 1930, V. 36, No. 5, p. 35.—Layout for typical interior floor bay shows seven of floor form panels marked F-1, signifying that they are all of same size and shape

and are interchangeable. Six other panels are marked F-2, which means that they are identical in size and shape and interchangeable. A special panel only 10 in. wide, marked F-3, is placed just off center line of floor bay, and is put there as aid to shoring of slab. Typical exterior floor bay layout contains greater variety of floor form panels. With such layouts in his possession, and knowing details, form carpenter foreman will know exactly how many floor panels of each type he will need for each of bays. With posts and girts in place, joists are set in place, but are not nailed or otherwise fastened to girts. Provision is made for substantial "permanent" shores near center of floor bay, by means of special floor form strip or panel. Before any of form work of floor bay is removed these shores are set into place under panel F-3 and fastened with wedges. Rest of form work in bay may then be removed as soon as it has attained sufficient strength to be self-supporting and to support weight of form work on floor above.—C. BACHMANN

DAMS

New Pardee dam a triumph in concrete construction. L. M. JORDAN. *Concrete*, June, 1930, V. 36, No. 6, p. 27.—Beginning of work of constructing Pardee dam across the Mokelumne river near Valley Springs, Calif., consisted of construction of flume to take care of river waters, and work of excavation for foundation was successfully conducted without interruption during winters of 1927 and 1928. Dam is 358 ft. in maximum height, 241 ft. in greatest base width, and has crest length of 1,337 ft. The contract called for completion of dam within 42 months. It was actually completed 1½ years ahead of schedule time. Cement was transported to dam site over 5-mile branch line of railway that was built by the contractor. Concrete aggregate material was secured from tailings of placer mining operations 4 miles down river. After gravel had been excavated by large dragline and transferred on cars to base of washing tower, it was elevated by means of a belt conveyor, and passed down through screens in washing tower. During months of August and September, 1928, the 18,700-ft. direct aerial tramway transferred concrete to dam at rate in excess of 67,000 cu. yds. per month. It had been designed for 440,000 lbs. capacity of gravel, or 147 buckets per hour. During 79-day period it transferred some 232,800 buckets of material from washing plant to bunkers. Four electrically-driven drum mixers were used, inclined into discharge chutes that concentrated materials into control hopper positioned on the hillside below plant, which discharged into a chute terminating at the base of principal concrete tower. Daily moisture determinations of sand were made from which moisture additions were calculated. Slump tests were practiced to arrive at the total water, but judgment was based principally upon the appearance of the concrete.—C. BACHMANN

Construction of weir in Chemnitz (Germany). R. PAPP. *Der Bauingenieur* (Germany), Jan., 1930, V. 11, No. 4, p. 55-8.—River Chemnitz is damned near site of electric power station in order to furnish sufficient water for steam boilers and cooling system. Station produces 84,300 kw. with 24 steam boilers which consume 8,000 to 12,000 cu. meter of water per hour. Old weir was replaced by new modern structure, construction of which is described. —A. E. BEITLICH

Dams of Oued Fodda and Ghrib. M. TRUFFOT. *Annales des Ponts et Chaussees*, (France) Jan.-Feb., 1930, No. 1, p. 41.—Two dams, of which former was begun in April 1926, and latter during second half of 1927, constitute a vast program of irrigation of Chéliff plain in Algeria. Total capital invested is estimated at 250 million francs. The energy produced will amount to about 14 million kilowatt-hours annually. Oued Fodda dam is a gravity dam of concrete with triangular section, 5 m. wide at the crown and 72 m. wide at the toe. It is 200 m. long. The volume of concrete to be placed is approximately

270,000 cu. m. The proportion of cement varies from 150 to 300 kg. per cu. m. of concrete. Expansion joints with copper plates are spaced every 18.6 m. The rock is transported from the quarry a distance of about 400 m. It is screened and stored in silos with automatic discharge, which permit mechanical proportioning of concrete. Proportions are selected with view to avoiding segregation in chuting concrete. Density of concrete varies from 2.4 to 2.6 and 2.7. Kieselguhr in quantities equal to 3 per cent by weight of cement is mixed with latter to increase strength of cement. No consistency tests are used—the only cue is the penetration of a man's foot (shod) up to the ankle. At the time of writing 350 to 400 cu. m. were being placed per day; it was expected to raise this production to 600 to 700 cu. m. per day.—MRS. M. A. CORBIN

Construction of the dam of San Joaquin. ADOLFO ORIVE DE ALBA. *Ingenieria* (Mexico), Jan., 1930, p. 22-25.—Methods employed in construction of an earth dam with reinforced concrete core wall are described. The upstream embankment was constructed with layers 20 centimeters thick of three parts of clayey earth and one part each of sand and gravel. Layers were given slope of 2½ per cent toward center of dam for about 10 meters and then levelled with idea that any tendency toward slipping would be in direction of center rather than toward outside. Downstream embankments differ in that proportions of sand and gravel, in each layer, increase from center to facing, which contains no clay. Clayey earth was excavated by power shovels about 500 meters upstream of dam, and conveyed by dump trucks to place. Sand and gravel were excavated by hand 50 meters upstream, and conveyed by wheelbarrows and baskets to place. Mixing and compacting of materials were done by tractor plows and rollers, with the mass wet but not fluid or muddy. All of the placing of earth fill was done under the supervision of inspector responsible for obtaining proper mixture and compactness. Average cost of embankment was $1.60 per cubic meter. Stone drain at foot of downstream face of dam was constructed of tailings and heavy gravel obtained from clearing bed of river at dam site. This material was loaded into special gondola cars by hand and dumped in place. The average cost in place of such stone transported 80 meters was $0.62 per cubic meter. Careful examination was made of the clay strata in which core or cut-off wall was to start. It was discovered that strata on which dam was originally founded in 1927 was underlaid by loose layer of water-bearing sand and gravel, which might have endangered the dam. Materials for concrete were thoroughly investigated before start to determine proper proportions. Abrams' curve for water-cement strength relation was taken as guide for the following proportions adopted as standard after experiment: 26 litres of water, 50 kilograms of cement, 63 liters of sand, 114 liters of gravel, and an eight centimeter slump. Two plant set-ups were made for pouring core wall. The first set-up used two one bag mixers, to which sand and gravel were fed by gravity from overhead volume batchers which were filled by wheelbarrows. Automatic batch meter was used, and a three minute mix required. Concrete was carried to dam in special gondola cars and then dumped into inclined chute, which in turn fed vertical tube. The second set-up became necessary after about 1000 cubic meters of total 2600 cubic meters had been placed, when concrete reached height of gondola cars. New set-up used only one mixer of two-bag capacity; and concrete was transported to dam by means of cable-way above crown of dam. This cable-way, not only supported gondola car, but also, chute into which it dumped concrete. Concrete was poured continuously day and night, and amounted to approximately 30 cubic meters per eight hours. Difficulty was encountered in getting form work properly and efficiently set up, despite careful preliminary design, because of

inexperience of available carpenters. A chart of the organization, which functioned well, is given.—MILES N. CLAIR AND C. G. CLAIR

MISCELLANEOUS

New method of conveying plastic concrete. GEORG GARBOTZ. *Tonind. Ztg.* (Germany), March 17, 1930, V. 54, No. 32, p. 372.—Conveying concrete from mixer to forms, by pumping through pipes, has often been unsuccessfully attempted. This "Pumpkret" process, as developed by Giese and Hell in Kiel, has been found very satisfactory on several jobs. Importance attached to this process is evidenced by formation, under leadership of Torkretgesellschaft, of an international group representing American, English and French interests, to perfect the process. Mechanical means now in use for conveying concrete, carts, cableways, chutes, and bucket belts are unsatisfactory either because of size or because of original and maintenance cost of plant. Chute method has also disadvantage of lowering quality of concrete due to extra water required. The Ransome Company with its "Concrete-Placer" conveyed plastic concrete through pipes by means of compressed air. Pneumatic method of Torkretgesellschaft is based on entirely different principle. Cement and dry aggregate, instead of wet concrete, are blown through pipes to point of pouring. At this place a water chamber provides necessary water. Bongardt process is similar to this, except that cement and aggregate are slightly dampened and are forwarded under lower pressure. Torkret process still has some disadvantages: comparatively high energy consumption and tendency to produce concrete of variable quality. In Giese "Pumpkret" method concrete is mixed in usual manner and flows into feed chamber, at the bottom of which is stirring arrangement that prevents segregation and passes concrete to vertical pump cylinder. Pump delivers it to air chamber from which it is forced through pipes with regular impulses. Pipes are of 2 mm. (0.078 in.) material and have no sharp bends. Vertical portions of line are attached to wooden frame or post and horizontal portions are placed on forms. Operation of equipment is simple. Motor, pump, feed-chamber, agitator, air chamber are mounted on four-wheeled frame. Erection of piping requires only few hours. One man is needed at pump and feed-chamber and one or two men at discharge end of pipe line. Aggregate used is not larger than 20 to 30 mm. (0.79 to 1.18 in.). Consistency of poured concrete is such that it barely flows around reinforcement. Concrete is of good quality and shows no evidence of segregation. Energy consumption is low compared to other processes: 12 H. P. for a 10 cubic meter (13.1 cu. yd.) per hour production delivered vertically 15 meters (49 ft.) and horizontally 15 meters. Against advantages of easy erection, small space requirements and simple operation there exist at this time disadvantages of limited size of aggregate and limited production, difficulties that should be overcome through further study. "Pumpkret" process represents definite advance in reinforced-concrete construction since it presents a conveying method more satisfactory from both economic and scientific viewpoint than any method heretofore employed.—A. A. BRIELMAIER

Instructions for concrete construction. Belgian Association for Standardization, 2nd edition, Aug., 1929. Reviewed in *Annales des Ponts et Chaussees*, (France), Jan.-Feb., 1930, No. 1, p. 65.—Belgian Association has attempted to work out a type of specification applicable on smaller jobs. Values are given for loading, shrinkage, variations in temperature. In discussing stresses, two methods are suggested. Former, in which no tests are made, makes use of four basic concrete mixes, stipulating grading of gravel, natural sand and varying proportions of portland cement, the Abrams cone test being used as indication of consistency. The allowable stresses are given for each of the 12 mixes

thus obtained. In second method, tests are made on 20 cm. compression cubes made under job conditions. The aggregate should be hard and clean; the choice of consistency may vary within certain limits of slump test. Ratio by weight of cement to water should exceed 1.30. Concrete should contain at least 250 kg. cement per cu. m. measured in place. It should be sufficiently compact and plastic to insure proper coating of reinforcement and avoid rust. Ratio by weight of inert particles smaller than 5 mm. to those greater than that size should be within 0.30 to 0.80. Allowable stresses will be equal to one third of the compressive strength of the cubes made in field (average of three tests) and tested at ages of 28, 14 and 7 days. Maximum allowable stresses given for four different cements vary from 50 to 90 kg. per sq. cm. Three test cubes should be made each day for first 15 days; whereupon three cubes are made each week. In no case should stresses allowable in reinforced concrete exceed those of plain concrete by more than 50 per cent. Allowable shearing stress in concrete, computed disregarding stirrups and inclined bars, should not exceed one fifth of the allowable compressive stress. Allowable bond stress should be: one tenth of the allowable compressive stress, when the ends of bars are not hooked; one fifth when hooked ends are provided. In former case stress is not to exceed 6 kg. per sq. cm.—in latter 12 kg. per sq. cm. Tensile and compressive stress of reinforcement may reach 1200 kg. per sq. cm. All parts of construction exposed to repeated load should have allowable stresses reduced accordingly, this reduction not to exceed 25 per cent. Cement used is to be one of three brands of portland cement, slow-setting, or special slag cement. If latter is used, field test method must be followed. Working of concrete shall continue until further mixing produces no change in consistency. Unless otherwise specified, tests of finished structure will be made at expense of the owner.—MRS. M. A. CORBIN

The drillhammer. "Der Bohrhammer." (New journal) Flottmann, A. G., Herne i. W. (Germany). Reviewed in *Zement* (Germany), May, 1930, V. 19, No. 20, p. 480.—Journal covers field of use and application of drilling in bridge and building construction, mines and quarries. Descriptions are given of jobs, and new inventions and improvements of equipment are discussed.—A. E. BEITLICH

Concrete as building material in American foundation jobs. H. GRIESEL. *Zement* (Germany), April, 1930, V. 19, No. 17 and 19, p. 400-2 and 452-5.—Description of methods of construction, which are generally used in America, with pre-cast concrete piles and such piles which are molded-in-place. Advantages of Raymond piles are characterized. Foundations for bridges, dams and large buildings are illustrated.—A. E. BEITLICH

Reinforced concrete for construction of coke plants. *Zement* (Germany), April, 1930, V. 19, No. 17, p. 409-10.—On account of its fire resistance, durability and economy reinforced concrete was used for a great number of modern coke plants. Construction of one is described in details. Storage bins and foundations of ovens as well as all buildings were built of reinforced concrete.—A. E. BEITLICH

Protection of metallic and non-metallic structural materials against corrosion. B. SCHEIFELE. *Der Bauingenieur* (Germany), Feb., 1930, V. 11, No. 7, p. 105-8.—Author illustrates different causes of corrosion of metals, concrete, reinforced concrete, artificial stones and wood and gives directions to prevent such action by successful protective methods.—A. E. BEITLICH

Applications of concrete construction with sliding forms. KNEES. *Zement* (Germany), June, 1930, V. 19, No. 24, p. 561-5.—Description is given of modern methods to save time and to reduce costs of forms and formwork. Special consideration is given to construction with sliding forms, which allows continuous use of one form for construction of bins, stacks, storage houses, tanks and similar structures. Different modern American and German methods are illustrated. Concrete is poured continuously without joints. Control of

homogeneity is very easy. Forms are raised in steps of approximately ¼ in. Average rate of progress is about 7 to 8 ft. per day but can be increased when high quality portland cements are used. Concrete leaves forms after approximately ten hours; after this time it is sufficiently hardened. Weight of forms, platform and laborers rests on foundations. No finishing of concrete surface is necessary since no form marks remain. Several photographs accompany article.—A. E. BEITLICH

Precast concrete caissons for piers and docks floated into place. P. W. LEISNER. *Concrete*, May, 1930, V. 36, No. 5, p. 30.—New patented method in harbor construction, successfully used in building new completed first portion of Polish harbor at Gdynia should be of interest to American builders. About four and a half linear miles of reinforced concrete floating caissons, rectangular in plan, were used in construction. Caissons were towed to their positions in harbor, sunk to rest on prepared sand and gravel foundation and given stability by sand fill. Largest caissons were 105 ft. long, 23 ft. wide and 35 ft. deep, divided into nine cells by vertical cross walls. Width of bottom, or base, was 30 ft. Weight was about 1200 long tons. Most caissons were made standard length of 60 ft., divided into five cells by vertical cross walls. Instead of following the usual practice of building these caissons in dry dock or on launching ways, contractors built them upon surface of land which was to be dredged for harbor basins. Caissons were cast in lying postion on ground, in long rows. As dredging proceeded, finished caissons gradually righted themselves on advancing slope until they floated. Dredging was done with suction dredges.—C. BACHMANN

Selling ready-mixed concrete in Erie. *Concrete*, June, 1930, V. 36, No. 6, p. 13.—Central mixing plant of the Charles H. Fry Construction Co. is well located with respect to receipt of materials and delivery of mixed concrete. A railway spur siding serves this plant exclusively. Washed sand and gravel are bought from pit about 12 miles away. Cement is received by rail, in sacks, and transported by portable conveyors to almost any point in the building. Gravel and sand are unloaded from cars to stock piles and from stock piles to bins. Plant is enclosed and roofed over, except sand and gravel bins at top. These have combined capacity of 18 cu. yd. Mixer, of 1 yd. capacity is charged by gravity from sand and gravel bins above, proportions being made by measure. Normal capacity of mixing plant may be considered 150 cu. yd. per 10 hr. day, but daily production of 175 cu. yd. has been attained. Two transit mixers of 1½ cu. yd. capacity, are supplemented by hired trucks when demand is heavy. Care is taken that water-cement ratio is held down to values consistent with various proportions. Grades of concrete supplied include 1:3:6 mix for footings and foundations in small buildings, 1:3:4 for sidewalks and floors, 1:2:4 for heavy foundation work and structural concrete work in general, and 1:1½:3 for heavily reinforced concrete work. Concrete has been delivered from plant for distances up to 16 miles, requiring about 50 minutes in time. Concrete delivered in city seldom requires haul of more than 3 miles, or 20 minutes. Base price for concrete (at plant) ranges from $7.25 per cu. yd. for the leanest mix, to $9.25 for the richest. The price for topping is from $12.00 to $14.00 per cu. yd.—C. BACHMANN

Concrete benches a necessity in greenhouses. WALTER B. BALCH. *Concrete*, May, 1930, V. 36, No. 5, p. 49.—Greenhouses use two types of soil containers. One known as a bed, is a pit in ground planked up to prevent caving of sides and to hold prepared soil in which plants are grown. Other is known as raised bench, or bench. Concrete beds built at the Kansas Agricultural Experiment Station were made 18 in. high above the ground, 3 in. at the base tapering to 2 in. at the top and extended 6 in. into the ground. Mix was 1:4 river run sand being used. Forms had to be built, but old bed walls and scraps served. For the raised beds, 1¼-in. pipe, set into block of concrete 8 in. square and 4 in. thick, was used for legs. Bottom of bench was made 3 in.

thick, and sides 3 in. thick at bottom, tapering at the top. To carry the load until the concrete had set, ¾-in. angle irons were placed across benches from leg to leg.—C. BACHMANN

Produces and delivers 3,700 cu. yd. of central-mixed concrete a day. *Pit and Quarry*, May 7, 1930, V. 20, No. 3, p. 51-54.—Description of two of Warner Company's three Philadelphia concrete plants—Berks St. yard and Christian St. yard. These receive aggregates by barges, the cement by rail in bulk. Plants are thoroughly up-to-date. Capacity of the Berks St. plant is 1,750 cu. yd. per day, that of Christian St. plant 1,000 cu. yd. per day. Eleven illustrations.—A. J. HOSKIN

West coast firm produces large volume of transit-mixed concrete. R. E. TREMOUREUX. *Pit and Quarry*, May 21, 1930, V. 20, No. 4, p. 57-58.—Describes practices of Golden Gate-Atlas Materials Co., San Francisco, Cal. Aggregates, cement, and water are measured and weighed at central plant, in batches of 4-cu. yd. each. Each batch is discharged into truck mixer which is air-tight when its doors are closed and which revolves enroute to its destination. Average mixing time is 15 min. Each of four cement tanks in plant holds 325 bbl. of cement which is handled from bulk-cement cars by pneumatic pumping. Three illustrations.—A. J. HOSKIN

ROADS AND PAVEMENTS

Concrete streets in Sicily. A. C. *L'Industria Italiana Del Cemento* (Italy), Dec. 1929, p. 8.—Article gives a description of a system of concrete street paving introduced by S. Ghilardi & Co., in which practice similar to that used in the United States is employed. Previously streets were poured in three layers, first of rich mix, second of lean mix of stone mixed with cement mortar, and third of average mix over which was plastered coat of special cement mortar. New procedure has been found to be decidedly better and consists of pouring total thickness as one layer and of one mix, applying surface mortar also contemporaneously or next morning using special quick hardening cement. —C. G. CLAIR AND M. N. CLAIR

Merchants of New Orleans beautify Canal Street. *Concrete*, May, 1930, V. 36, No. 5, p. 47.—In the improvement of Canal St. in New Orleans all old walks were removed, regardless of their condition and new walks 5 in. thick were laid in their place. Top portion was divided into squares, by brass strips, and red border 23 in. wide was made along curb and property line. Coarse aggregate for uncolored portion of top was one part Crown Point spar and one part white marble. For red border aggregate was pink Georgia marble. The red border was obtained by mixing red iron oxide into concrete.—C. BACHMANN

Various municipal works in Bromley. H. CLIFFE. *Contr. J.* (England), June 18, 1930, V. 102, No. 2662, p. 1975.—Concrete carriage ways were constructed on continuous system, a straight joint being left at end of each day's work; expansion joints were provided 150 ft. to 150 yd. apart. It was found difficult to provide satisfactory channel when tamping from the curb so 4 in. thickness of concrete 3 in. wide was laid alongside the curb floated into proper channel levels, a 4 in. by 3-in. timber being placed on such floating and carriageway tamped therefrom. When timbers are afterwards withdrawn, space is filled with fine tarmacadam, the result proving very satisfactory. In carriageways constructed in two widths, 3 ft. long rods were placed at 12 in. centres along joints, and allowed to project 18 in. from first half width laid. Only minimum water for hydration was permitted and concrete was cured with moist sand.—JOHN E. ADAMS

Overcoming paving difficulties in West Virginia. *Concrete*, May, 1930, V. 36, No. 5, p. 13.—District No. 5, West Virginia highway department comprises ten counties lying along the crest of the Allegheny highlands and encompassing the Potomac region. Because of mountainous country and un-

certain subgrades encountered, the district constructs its subgrades at least one year ahead of paving. Slides and movement in roadbed are every-day occurrences. Any pavement laid on new subgrade is almost sure to settle or move out of alignment. Once the subgrade is built, traffic is turned over the road and kept on the new location during the settling period. Grading usually entails moving from 15,000 to 50,000 cu. yds. of material. Much of work is in rock formation, unstable in many cases and prone to slide in others. Curves are frequent, banked as much as 36 in., and are made with as long radius as possible. Embankments are built around curves and along sides of cuts or along drop side of side-wall roads, taking form of heavy-base bank with a curve approaching a parabola. District Number 4, comprising twelve counties, lies to west of District 5, and while its eastern part is mountainous it slopes downward toward the Ohio valley in long rolling ridges. Extensive mining has undermined territory with honeycomb of galleries which cause settling and changing contours of surface land. Peculiar land slides have also occurred, resulting in an unlooked-for elasticity of concrete pavement. This elasticity has led to adoption of somewhat unusual practices in reinforcing slabs. Engineers have come to know just where probable movements will take place, and when another location is impossible extra reinforcing is incorporated. Steel is saved in stretches where it is not urgently needed and accumulated excess is put into slab where movement is likely to occur. Location has been turned to as only means of preventing great expense involved in efforts to overcome force of slides and settlement. Cutting subgrade back into rock or locating right-of-way along ridges or in valley bottoms is engineer's only assurance of permanency.—C. Bachmann

Water Works

New water pipes of public water works of city of Munich (Germany). Lutz Pistor. *Zement* (Germany), May, 1930, V. 19, No. 22, p. 516-7.—Drinking water supply for city of Munich is furnished by wells which produce water of high purity. Two pipes of approximately 50 km. length deliver water to water works. Construction of third pipe was necessary to cover requirements of growing population. Greatest part of this work was done under ground. Cross-section of tunnel was 5.5 $m.^2$ Conditions of ground and surface were very varying. Wall of pipe was 35 cm. thick. Total of 140,000 cu. meters of ground were removed, 60,000 cu. meters of concrete were placed and 120,000 m^2 inner surface were provided with very smooth finish. Aggregates, which were found near the job, were washed free from loam. Wells were drilled to obtain sufficient water for this purpose. Concrete mixer and distributing arrangements were located under ground. Conveyer belts and electric driven cars delivered material to laborers who placed concrete behind forms. Work was continued during winter. Aggregates were heated by means of steam pipes in bins.—A. E. Beitlich

Shop Manufacture

Detroit concrete block plant on large production basis. M. B. Williston. *Concrete*, May, 1930, V. 36, No. 5, p. 17.—Concrete products manufacturing plant of R. E. Hamilton's Sons, Inc., in Detroit, is arranged and equipped for manufacture of all sizes and shapes of solid and hollow concrete units on a large production basis. The company manufactures cinder concrete units in complete line of more than 50 different sizes and styles, as well as art stone, chimney blocks, pier caps, sills, coping tile and related specities. Production capacity is 18,000 units per day of gravel concrete block and 7,000 daily in cinder unit department. Block machines in main building consist of two automatic standard strippers each producing 6 units, and one master tamper producing 4 units per minute. In cinder unit plant there is one automatic super-stripper producing 8 units per minute. Two block racks are set

side by side on a small revolving platform, for removing newly made block. Man removing block from machine fills one rack, when platform is immediately revolved 180° This rotation brings the empty rack next to block-making machine and loaded rack on other side. Louden overhead monorail system is used in transporting newly manufactured units from machine to curing chamber and later from curing chamber to all parts of open-air storage yard. Each trolley has 8 small wheels which run on the lower flange of a continuous I-beam. Entire block manufacturing operations are handled by plant superintendent and 20 men.—C. BACHMANN

Twenty-five different units with one power stripper. *Concrete*, April, 1930, V. 36, No. 4, p. 19.—Two outstanding features about plant of the Crown Sidewalk and Block Co., Minneapolis, Minn., are the kitchen-clean appearance of stock yard and remarkable range of style and sizes of masonry units produced. Twenty-five standard units are made on one Anchor power stripper machine, equipped with quick-change attachments for production of all standard and special sizes, styles and faces required. There are 25 different piles of blocks in yard at all times, displaying as many different kinds or sizes of units.—C. BACHMANN

Concrete molds. *Rev. materiaux construction trav. publics* (France), Feb., 1930, No. 245; p. 69-70.—Molds made of concrete composed of fine sand and cement only are used for manufacture of objects of unusual shapes, to obtain very smooth surfaces and clear cut edges. At moment of making mold, concrete must be very liquid to penetrate into all the interstices. There are several methods of making these molds.—A. SIZE

Plant producing ready-mixed concrete and cement products. *Pit and Quarry*, June 18, 1930, V. 20, No. 6, p. 28-29, 60.W. G. Traver Supply Co. operates two adjacent plants in Decatur, Ill., one producing ready-mixed concrete, the other manufacturing concrete blocks and other cement products. All aggregates—sand, gravel and crushed stone—are received by rail. Mixing plant capacity is 150 cu. yd. per 9-hr. day. Aggregates, as received, are dumped into concrete hopper whence they are taken by a chain-bucket elevator, through divided hopper into two circular wooden tanks, each of 4-carloads capacity, one being used for sand, one for gravel or stone. Each bin has two gates. One gate discharges to trucks in concrete tunnel, the other to volume batcher where cement and Celite are added from sacks. Batcher discharges into 28-cu. ft. mixer, and charge is mixed from 3 to 5 min. Water is measured from a tank having calibrated glass gauge. Cement is bought in sacks and carried from cars to the mixing floor by a slat elevator. Concrete is delivered in trucks with dump bodies. Block plant is new, and is of concrete, concrete-block and structural steel construction. Elevator which supplies the mixing plant supplies this block plant by discharging through a separate chute to inclined belt conveyor which runs to top of building. Materials are discharged into two large wooden tanks, each of which is divided into two sections, thus providing separate storage of sand, gravel, crushed stone, and haydite. Slat elevator previously mentioned feeds a belt conveyor which carries cement and Celite to block plant. Bin compartments discharge to 14-cu. ft. batch hoppers. Hoppers discharge to 32-cu. ft. steel car which serves 21-cu. ft. mixer. Prepared mixture discharges into stripper block machine which has made more than 3,200 blocks in 9½-hr. day. Blocks are loaded onto steel racks and hauled on lift truck into curing kilns where they remain 36 hr. at temperature of 76°. Air is forced through kilns by compressor. Heated water supplies heat and humidity by discharge through valves into fog-like spray. Hydraulic jack is used for testing concrete cylinders and block. Six illustrations.—A. J. HOSKIN

Materials

Admixtures

Influence of admixtures of loam in sand upon mechanical properties of portland cement mortars. M. G. Jeltschaninoff. *Zement* (Germany), June, 1930, V. 19, No. 24-5, p. 556-60, 580-5.—Experiments concerning influence of loam in sand were subject of comprehensive investigation. Following conclusions were drawn: Loam admixtures in sand are in general unfavorable. Sand may be used containing not more than 2 per cent pure loam. Organic materials in loam are of great importance. Tests must be extended over long period, at least several months. Loam should not be dried before tests. Both tensile and compressive strength must be examined. Question of influence of loam is not entirely solved and must be further studied.—A. E. Beitlich

Rhenish trass from the neighborhood of Eifel. K. Biehl. *Ciment* (France), July, 1930, V. 35, No. 7, p. 266-8.—Trass was secured by Romans near Eifel and used in concrete water conduit from that place to Cologne. Parts of the conduit still remain.—F. O. Anderegg

Aggregates

Application of Trilinear charts to aggregate grading control. Theodore E. Sheafer. *Concrete*, April, 1930, V. 36, No. 4, p. 33.—The method of plotting a trilinear chart is explained by example, using four different gradings of sand, indicated by a, b, c and d, the sieve analyses for each being given. The chart is labeled to correspond with the three sieve sizes, No. 14, No. 28 and No. 100. The application of trilinear charts to aggregate grading control is also given in form of a typical example. By carrying in stock three sands of different grading, namely, a coarse sand (C), a sand of medium fineness (M), and a very fine sand (F), the grading of the combined sand (S) can be controlled by selecting the proper proportions of the three sands according to the methods described.—C. Bachmann

Volcanic slag and similar mineral rocks in the region of the Lake Laach (Germany). Otto Gassner. *Zement* (Germany), July, 1930, V. 19, No. 28, 29, p. 658-60, 682-7.—Volcaneous rocks and slags of this region, such as basalt lava, volcaneous slag, tufaceous rocks, pumice and trass are of importance in concrete practice. These materials originate from eruptions of former volcanoes. Their formation and physical properties are described and strength specifications discussed. Special consideration is given to volcaneous slag. Mines are driven into deposits until material collapses. Dump cars transport broken masses to screen which separates them into sizes of 30, 40 and 50 mm. Coarses portion goes through crusher. Conveyer belt delivers material to storage bins. Chemical composition shows great uniformity and no constituents are present, which have unfavorable influence on cement or hardening process. Slag has very good hydraulic properties and shows great resistance to frost. Experiments indicated that concrete with this slag as aggregate also showed great resistance and less decrease in strength when exposed to fires, than concrete which was made with gravel. High heat-insulating properties make it a valuable material for building construction. Data are given for different concrete mixtures and strength properties are compared. A number of further possibilities for use of material are cited. —A. E. Beitlich

Control and improvement of the grading of sand, gravel and pebbles used as aggregate in concrete. Adolf Janousek. *Le Ciment* (France),

June, 1930, No. 6, p. 245.—Author gives report of extensive tests to determine approximate volume and surface area of aggregates. Sieves selected were similar to standard American sieves. The pebbles were taken from bed of the Vetava near Prague. Ellipsoids of three axes, slightly angular, were substituted for round and elongated pebbles. It was found that 138 pebbles of 15 to 30 mm. were equivalent in surface area and volume to 218 imaginary spherical pebbles of 15 mm. diameter. As concrete strength depends not only on dimensions of aggregate, but on surface area as well, this is of great importance, particularly in connection with tensile strength of concrete. Parallel tests were made grading the aggregate in accordance with Fuller's curve, Abrams' fineness modulus and using only fine sand and coarse pebbles in the third series. The most instructive mix was a tamped concrete of "moist" consistency with 3.84 liters water, 60 kg. sand and dry pebbles and 9.6 kg. high test portland cement. While the mixes contained equal quantities of mixing water and cement and had the same fineness modulus, their strengths varied greatly. The author urges that sieve analysis be made a part of regular field tests of concrete. To simplify procedure he recommends a set of five sieves of 1, 3, 7, 15 and 30 mm. for the coarser materials and 1, 2, 5, 10 and 20 mm. for the finer materials. The curves obtained resemble the Fuller curve. The allowable discrepancies would be ±5 per cent of the total weight of the material analyzed.—M. A. CORBIN

The economic use of separate aggregates and the automatic regulation of the water addition to obtain a uniform concrete. OSKAR SPETZLER. *Die Bautechnik* (Germany), Feb., 1930, V. 8, No. 9, p. 130-2.—Advantages of separate addition of gravel and sand for manufacture of dense concrete are described. Quality of concrete depends on (1) quality and amount of cement, (2) quality and gradation of aggregates (3) amount of water and (4) good working and finishing of concrete. Amount of water must be changed with varying moisture contents of aggregates. This change can be prevented when sand is saturated with water before entering mixer. Mixing equipment for accurate measuring of materials and production of uniform concrete is described.—A. E. BEITLICH

Effect of soft particles of coarse aggregate on strength and durability of concrete. W. J. EMMONS. *National Sand Gravel Bull.*, June and July, 1930. V. 11, No. 6, p. 9-16, No. 7, p. 9-14.—Report was first presented before the Sixteenth Annual Conference on Highway Engineering, Ann Arbor, Michigan, and published in Proceedings of that conference. It covers results of an investigation carried out by State Highway Laboratory of Michigan to determine effects of certain soft and non-durable particles, occurring locally in gravels, on strength and durability of concrete. Soft particles studied in this investigation included three classifications of sandstone (hard absorbent, intermediate or borderline, and soft) shale, ochre, and a curious light weight, porous, fossiliferous, dolomitic material, colloquially known as floaters. Gravel used as the basis of comparison was hand picked practically free of soft particles. Concrete specimens were made using standard gravel to which was added 0, 2, 3, 5, 10 and 15 per cent of each of the types of soft particles being investigated. Three groups of specimens were made for each percentage and type of soft particle,—a set of specimens consisting of two beams and three cylinders. First group was tested after normal moist air curing for 28 days; second after 25 alternations of freezing and thawing carried out subsequent to 28 days of normal moist air curing; third group has not yet been tested, being held for long-time tests. Author concludes that "after reviewing data here presented there can be little doubt that presence in concrete aggregates of materials studied is injurious. The normal strength of concrete is reduced and liability of deterioration under freezing and thawing conditions is greatly increased. Much of effect of these materials upon

both strength and durability is dependent upon location of particles in structure, and neither in the laboratory nor in the field can this factor be controlled. A far more extensive investigation, involving concretes of different proportions and exposure under many conditions would be necessary to determine, within reasonable range of accuracy, quantitative measures of these effects under service conditions. That such an extended study would be worth while, is doubtful, for the several general types of the undesirable materials are themselves of rather indefinite and variable classification, and not susceptible to accurate definition. In areas where such soft and structurally unsound materials occur, however, this investigation does unmistakably point to the desirability of reducing. to economic minimum, their percentages in coarse aggregate."—STANTON WALKER

CEMENT

Revised procedure for the determination of uncombined lime in portland cement. WILLIAM LERCH and R. H. BOGUE. *Ind. Eng. Chem. Analytical Edition.* July 15, 1930, Vol. 2, No. 3, p. 296-8.—Revised procedure for determination of uncombined lime in portland cements by ammonium acetate titration method is presented. Various factors which bear on precision of test are discussed. A curve is given which shows that percentage average deviation from mean varies with mean value for uncombined lime. The probable errors have been determined and a curve is given which shows probable error of any group of determinations from mean, at any mean uncombined lime content up to 7 per cent.—R. N. YOUNG

Mortars and cements in ancient history. F. GOLDSCHMIDT. *Zement* (Germany), June, 1930, V. 19, No. 23, p. 543-4.—Asphalt was frequently used as building material in countries where it was found; it was good binder and weather resistant. Gypsum and lime were most common mortars. It cannot be determined whether additions of sand were made or if sand, which was found in the analyses was incidentally in raw materials. In dry countries a favorite mortar was clay or loam, mixed with straw, but only suitable for smaller buildings.—A. E. BEITLICH

Rotary kiln calculation. A. B. HELBIG. *Zement* (Germany), June, 1930, V. 19, No. 24, p. 568-9.—Continuation of polemic between author and Hans Bussmeyer on the subject of comparison of heat economy of "Lepol"-kiln and ordinary rotary kiln with waste heat recovery. (c. f. A. B. Helbig, *Zement* (Germany), May, 1930, V. 19, No. 19, p. 440-4 and H. Bussmeyer, *Zement* (Germany), May, 1930, V. 19, No. 22, p. 522-4.)—A. E. BEITLICH

Rotary kiln calculation. HANS BUSSMEYER. *Zement* (Germany), July, 1930, V. 19, No. 29, p. 680.—Last article concerning polemic between author and A. B. Helbig about superiority of "Lepol" kiln over rotary kiln with waste heat recovery. (cf. A. B. Helbig, *Zement* (Germany), May 1930, V. 19, No. 19, p. 440-4 and June 1930, V. 19, No. 24, p. 568-9; Hans Bussmeyer, *Zement*, May 1930, V. 19, No. 22, p. 522-4.)—A. E. BEITLICH

Control of reactions in rotary kiln. *Zement* (Germany), June, 1930, V. 19, No. 23, p. 536.—Description of sampling device designed by W. H. Lacey and Hubert Woods, which enables sampling of clinker at different parts of rotary kiln during burning process. Samples from front end of kiln were taken by means of long iron pipe with attached sample container. Samples from middle and end of kiln were taken through holes which were drilled through shell and lining. Holes were provided with special caps. Arrangement worked very satisfactory. Determinations of free lime and ignition loss showed rate of combination and enabled burning control. (c. f. *Rock Products*, Jan. 1930, No. 2.)—A. E. BEITLICH

About formation of dusting clinker. J. MUNDORF. *Zement* (Germany), June, 1930, V. 19, No. 26, p. 608-9.—A mixture of 40 per cent blast

furnace slag and 60 per cent limestone was burned in a shaft kiln. Coal was mixed with raw mixture. Produced clinker was very satisfactory until recently when product showed very great amount of dusting clinker. Reason for this behavior was an increasing amount of metallic iron up to 8 per cent in slag which lowered fusion point and prevented air from passing through clinker. Uncomplete combination of raw materials resulted. Burning process was under reducing conditions, an amount of 8 per cent of CO was found in the stack gases. Ferric oxide was reduced to FeO and metallic iron. Since Fe and FeO do not combine with CaO an excess of lime was present which fact made conditions worse. After replacing high iron containing slag by good slag, product was of satisfactory quality.—A. E. BEITLICH

Methods of investigating the thermochemistry of cement. W. A. ROTH, *Zement* (Germany), July, 1930, V. 19, No. 27, p. 628-30.—Reactions under investigation are formation of clinker from raw materials and setting and hardening process of cement. Direct calorimetric measurements are impossible to obtain. Heat tones of these reactions can be studied indirectly by determining heat of solution. Best solvent is mixture of 100 parts of hydrochloric acid (20 per cent) and 15 parts of hydrofluoric acid (20 per cent) which dissolves all constituents. Metal container with inner gold lining can be used as calorimeter. Solution can be accelerated by (1) very fine pulverization in order to expose great surface to action of acid, (2) great agitation in calorimeter, (3) higher concentration of the solvent and (4) starting of reaction at higher temperature than room temperature. Experiments were made at 50 and 100° C. Second way to attack this problem is to study heat of formation of end products. Raw materials are burned in calorimeter with paraffin oil as fuel, the heat of combustion of which is determined very accurately. Results obtained directly by this method are very satisfactory. Specific heat of components must be determined in order to calculate results for room temperature or temperatures in cement kiln.—A. E. BEITLICH

Influence of fineness on strength of portland cement. HANS KUHL. *Zement* (Germany), June, 1930, V. 19, No. 26 and 27, p. 604-8, 630-3.—Investigations were carried out to find best particle size of cement to obtain high strength properties. Finest cement portion does not give highest strength. Two cements were separated into 7 fractions from 10 to 60 μ by means of a Gonell air separator. Surface of particles was measured with formula derived by author. Rate of grinding and reaction of cement with water can be expressed by measured surface. Tensile and compressive strength tests with small briquets and cylinders were made after 3 and 7 days. Special care was taken for accurate weighing of cement, sand and water. Saturated gypsum solution was used to prevent quick setting of finest particles. Interesting relations were found between surface and "value-factor," which is calculated from strength data. High strength was obtained with uniform composition and particles of 30 μ size. Mixtures of certain fractions were made and their strength studied. Very fine ground cement can be improved by adding coarser portions within small range; it is not ecomomic to grind cement of uniform size to extreme fineness. Additions of 30 per cent of very coarse cement can be made without considerable loss in strength to a very fine but not uniform cement. The following conclusions were drawn: good cement can be made by grinding material to uniform size, but not too fine, or by grinding to very great fineness and adding coarse cement. Investigation will be continued.—A. E. BEITLICH

Substitution of compression for tension tests as standard tests of cements. *Revue des Mat. de Constr. et des Trav. Publ.*, July, 1930, No. 250, p. 253.—A superior Committee for Standardization was organized in France effective May 1, 1930. Its purpose is to coordinate methods of construction all over France and to bring about standardization. First steps to be taken

by the Committee are official recognition of new types of cement not covered by last standards, the substitution of compression for tension tests, the corresponding readjustment of various types of cement and their official nomenclature. Arguments in favor of substitution of compression tests are presented by R. Feret, Director of the Ponts et Chaussees Laboratory at Boulogne-sur-mer. The proposed limits of compressive strength for portland cement are: 100 kg. per sq. cm. at 7 days and 160 kg. per sq. cm. at 28 days. Strengths for high test portland cement are: 100 kg. per sq. cm. at 2 days; 250 kg. per sq. cm. at 7 days and 320 kg. per sq. cm. at 28 days.—M. A. CORBIN

Spanish specifications of February 25, 1930, for acceptance of cements on public works. *Le Ciment*, July, 1930, No. 7, p. 278.—Separate chapters are devoted to portland cement, high test cements (alumina cements), supercements, slag cements puzzuolan cements and Zumaya (natural) cements. The minimum tensile strength of 1:3 portland cement and standard sand mortar is specified as: 19 kg. per sq. cm. at 7 days (1 day in air, 6 in water) and 23.5 kg. per sq. cm. at 28 days (1 day in air, remainder in water). The minimum compressive strength is specified as: 190 kg. per sq. cm. at 7 days and 280 kg. per sq. cm. at 28 days. For alumina cements the tensile strength required at 24 hr. shall not be less than 28 kg. per sq. cm. and shall attain 60 kg. per sq. cm. at 3 days. The concrete strength tested on 20 cm. cubes of 840 liters gravel, 400 liters sand, 300 kg. cement and 130 liters water shall be greater than: 220 kg. per sq. cm. at 24 hr. and 230 kg. per sq. cm. at 28 days. The tensile strength of 1:3 mortar made with super-cement shall be: 25 kg. per sq. cm. at 3 days; 30 kg. per sq. cm. at 7 days; 38 kg. per sq. cm. at 28 days. The compressive strengths shall be: 250 kg. per sq. cm. at 3 days; 350 kg. per sq. cm. at 7 days and 450 kg. per sq. cm. at 28 days. The concrete strength shall be: 180 kg. per sq. cm. at 2 days and 230 kg. per sq. cm. at 7 days.—M. A. CORBIN

The Spanish cement specifications. C. R. PLATZMANN. *Zement* (Germany), July, 1930, V. 19, No. 30, p. 701-2.—In Feb. 1930, great changes in Spanish standard cement specifications of 1919 were made. New directions include portland cement, high early strength portland cement, alumina cement, blast furnace slag cement, puzzuolan cement and Zumaya cement. Latter is kind of natural cement. Comparison of old and new specifications for chemical composition, fineness, setting time, soundness and strength properties are given.—A. E. BEITLICH

Roller bearings in the cement industry. BELANI. *Zement* (Germany), July, 1930, V. 19, No. 28, p. 654-7.—Author discusses different types of roller- and ball-bearings which can be used in cement industry. Economic point of view is given. Advantages of certain types for special purposes are described. —A. E. BEITLICH

Experiments with mixed cements consisting of high alumina cement and ground basic blast furnace slag. WILLIAM PETRY. *Zement* (Germany), July, 1930, V. 19, No. 29, p. 674-8.—Mixtures were made from high alumina cement "Alca" and blast furnace slag in following proportions: cement : slag : sand, 1:0:3; ¾:¼:3; ½:½:3, and ¼:¾:3. Compressive and tensile strength tests were made after 3, 7 and 28 days. Results showed that no great decrease in tensile strength takes place when one half of cement is replaced by slag. This mixture gives compressive strength which is much higher than strength which is demanded by standard specifications. Not more than half of cement should be replaced by slag. Additional tests were carried out in order to investigate action of different salt solutions, such as magnesium sulphate (5 per cent), sodium sulphate (4 per cent), sulphuric acid (1 per cent), acetic acid (1 per cent) and ammonium sulphate (5 per cent). General appearance and tensile strength after 15 months storage of test pieces, which were immersed in these solutions, showed that action of first

four solutions is considerable lower when one half of cement is replaced by slag. Only ammonium sulphate solution produced great deterioration in every case.—A. E. BEITLICH

The heat in the finishing mill and the setting time of cements. HEISER. *Zement* (Germany), July, 1930, V. 19, No. 29, p. 679-80.—Discussion of research work done by K. Koyanagi (*Zement* (Germany), May 1930, V. 19, No. 20.) concerning influence of heat during grinding process of cement on its setting time. Based on own investigations author comes in general to different conclusions and claims that quick setting cement is not necessarily produced when temperature in finishing mill is very high. With temperatures up to 100° C. he still obtained normal setting clinker.—A. E. BEITLICH

The sealing of rotary kilns, dryers and similar equipment. ERICH SCHIRM. *Zement* (Germany), June-July, 1930, V. 19, No. 23, 24, 26 and 27, p. 545-8, 570-2, 618-20, 642-4.—Several different types of seals are described. Discussion shows which types are suitable for special purposes. All advantages and disadvantages are illustrated and directions are given to prevent excessive wear. Seventeen photographs are reproduced.—A. E. BEITLICH

Experiments with a compeb mill using special steel fillings. OTTO FREY and MOSCHITZ. *Zement* (Germany), July, 1930, V. 19, No. 28, p. 652-4. —Experiments were made with a three-compartment compeb mill to increase efficiency by studying best combination and weight of various steel fillings with different shapes. Best results were obtained with filling of steel balls in first compartment, special patented "Kordt-balls" in second and steel cubes with small steel balls in third compartment. With usual filling of steel balls in first and second and "Cylpeps" in third compartment 12,500 kg. material was ground in one hour to fineness of 2.5-4 per cent residue on 4900 mesh sieve. With new filling 15,000 kg. was ground in one hour to fineness of 0.5 per cent residue on 4900 mesh sieve. Power consumption was 540 H. P. instead of 520 H. P. Material was clinker for production of special high early strength cement.—A. E. BEITLICH

Scientific research. *Structural Engineer* (England), August, 1930, V. 8, No. 8, p. 302-3.—The use of "hot cement," meaning cement which still retains much of frictional heat of grinding, has been found by Building Research Department (Bulletin No. 7) to have unimportant effects when used "under conditions likely to be found in a job." Tests reported in Building Research Special Report No. 15 are said to prove that coal residues are definitely unsuitable for use as aggregates in concrete reinforced by or in contact with steel. Sulphur contents of materials are considered to be prime cause of corrosion, and porosity and permeability to be of minor significance. —V. P. JENSEN

Production of Norwegian cement industry. *Zement*, (Germany) May, 1930, V. 19, No. 22, p. 525.—Data are given which show progress in production of cement in Norway during last 20 years.—A. E. BEITLICH

Studies of the behavior of cement mortars in hot water. Experiments made at the laboratory for testing materials of the Technische Hochschule in Stuttgart (Germany) during the years 1928 and 1929. "Versuche ueber das Verhalten von Zement-moertel in heissem Wasser." OTTO GRAF. German committee for reinforced concrete, publication No. 62. Willhem Ernst und Sohn, Berlin 1930, R. M. 4.30. Reviewed in *Der Bauingenieur* (Germany), June 1930, V. 11, No. 24, p. 427.—Book describes investigations of behavior of mortars exposed to water of different temperatures and under different conditions. Four kinds of cement, two

portland cements, one high early strength portland cement and one high alumina cement were tested at 20, 50 and 90° C. Compressive and tensile strength of 1:3 and 1:6 mixtures were studied. Behavior of cements was very different. Loss in strength is discussed. Steam of 50° C. has improving effect on samples while water storage at 50° C. reduces strength. Author derives theory about setting of cement and its solution process.—A. E. BEITLICH

Burning of cement on a chain grate. ERICH SCHIRM. *Tonind. Ztg.* (Germany), July 24, 1930, V. 54, No. 59, p. 978-81.—The application of chain grate principle to burning cement and lime to reduce the fuel requirements. Trouble is that clinker sinters to the grate and Lellep has proposed (German pat. 466,298) to use the chain grate for calcining and rotary kiln for clinkering. Result is much saving in space. It is claimed that the chain grate makes effective dust and heat remover from the gases. Average requirement of less than 2000 B. T. U. per lb. of clinker is claimed.—F. O. ANDEREGG

Apparatus for laboratory control of fineness of cements and description of several experiments carried out with this equipment. A. H. M. ANDREASEN and J. J. V. LUNDBERG. *Zement* (Germany), July, 1930, V. 19, No. 30-31, p. 698-701,7 25-7.—Description of apparatus to determine fineness of cement in which sample is mixed with liquid media. Ethylene-glycol was found to be best liquid for this purpose which gives suspension free of coagulation without peptonizator. Its specific gravity at 20° C. is 1.112 and its viscosity at 20° C. is 0.214 which covers correct range for particles from 5 to 100 μ. Experiments were carried out with (1) two portland cements, (2) one blast furnace slag cement, (3) one French high alumina cement, (4) calcined magnesite and (5) stucco. Apparatus allows continuous taking of samples and gives results of high accuracy. Blast furnace slag cement shows some tendency to coagulate but gives good results. Strong coagulation was found in case of alumina cement which could be prevented by addition of cobalti chloride (0.005 mol per liter). Magnesite gave fairly good results in pure glycol. Mixture of 50 volume per cent absolute alcohol and 50 volume per cent glycol with specific gravity of 0.964 and viscosity of 0.0497 at 20° C. and an addition of potassium citrate (0.005 mol per liter) was used for stucco. Tables showing results obtained and several references are given.—A. E. BEITLICH

New means for protection of concrete against acids and aggressive waters. *Chemiker Zeitung* (Germany), Apr., 1930, V. 54, No. 27, p. 259-60. —Description of properties of number of new water-glass cements. It is claimed that they are acid proof and can be manufactured with quick and slow setting properties. Hardening is not influenced by any weather conditions and can also take place, when no air is present. Good cementing material for bricks of acidproof tanks, acid towers and sewage pipes. Temperatures up to 800° C. do not affect cement. It can be used with advantage for linings of concrete structures and foundations exposed to acid sprays or drops. —A. E. BEITLICH

Obtaining finely ground raw materials for cement. J. GUERIN. *Ciment.* (France), July, 1930, V. 35, No. 7, p. 262-6.—Rapid recirculation combined with filtration gives best results.—F. O. ANDEREGG

The reliability and predictive value of short time tension tests of portland cement. H. WALTER LEAVITT and JOHN W. GOWEN. *Maine Technology Exp. Sta. Bull. No. 25,* June, 1930, V. 16, No. 2, 8 pages.—Increased use of portland cement and advent of so-called super-cements have

caused highway engineers to demand more rapid tests for mortar strength than formerly. It has been shown that 7-day tensile strength tests will give fairly accurate prediction of 28-day tensile strength of portland cement. (c. f. "The prediction of 28-day tensile strength of portland cements from their 7-day strengths" by John W. Gowen and H. Walter Leavitt, Bulletin No. 15, pp. 1-14, May, 1926. Also "Relation of 7-day to 28-day compressive strength of mortar and concrete" by John W. Gowen and H. Walter Leavitt, Bulletin No. 17, pp. 1-13, Maine Technology Experiment Station, October, 1926.) This paper gives data on 150 samples of portland cement of many different brands as received at the Testing Laboratory for the latter half of the year 1929. It was shown that the variability of any briquet from a series of three made from the same batch does not change much either in a 1-day, 3-day, 7-day or 28-day tests. This conclusion was derived by a statistical study of the data in hand. The predictive value of the 1-day, 3-day and 7-day tests was determined and the following coefficients derived: 1-day, 3-day and 7-day tension vs. 28-day tension give correlation coefficients of 0.322 ± 0.049, 0.395 ± 0.047 and 0.734 ± 0.020 respectively. Previous study in 1926 showed 7-day tension vs. 28-day tension giving a correlation coefficient 0.654 ± 0.015. Higher coefficient obtained in 1930 is partly explained by better quality of cements now on market and partly by better technique in methods of testing. The conclusions were: (1) Inter-relation of one briquet with another in 1-day, 3-day, 7-day, and 28-day tests are relatively high. (2) The 7-day tension tests give much more reliable prediction of 28-day tension tests than 1-day or 3-day tension tests. (3) Data should be produced to show superiority of any other age period over 7-day period before discarding old preliminary test age (7-day) period.—H. WALTER LEAVITT

New 2,000-bbl. wet-process cement plant nears completion in Southwest. *Pit and Quarry*, July 2, 1930, V. 20, No. 7, p. 47-50 and 54.—New plant of American Portland Cement Co. at Foreman, Ark., is straight-line layout with provision for doubling capacity. Rock is chalky limestone of uniform quality. Quarry cars will be hauled by locomotives to trestle over hopper. Rock will be crushed to ½-in. size and coveyed to steel bins or diverted to open storage. Clay will be obtained from neighboring pit. Clay-slip from concrete washmill will be pumped to steel storage tank and thence it will pass to raw grinding tube-mill with rock. Ground material will pass to agitated slurry slump, and thence to storage tanks equipped with agitators. From these tanks, slurry will be pumped to correcting basins and thence to kiln feeder. Kiln is 11 ft. 3 in. in diam. and 300 ft. long, electrically welded throughout, with four tires. Clinker will pass to a vertical cooler with sloping shelves and sprays of water. Cement will be pumped pneumatically to 12 storage silos of a combined capacity of 100,000 bbl., from whence it will be pumped to packhouse containing three packers. 16 illustrations.—A. J. HOSKIN

Cement plant's capacity can be trebled without stopping operation. *Pit and Quarry*, July 2, 1930, V. 20, No. 7, p. 51-53.—At Rosedale, N. Y., plant of Century Cement Corp., rock occurs in two beds separated by 15 ft. of impure limestone. Excavation is by room-and-pillar underground method, in each bed. Mined rock from two sets of workings is kept separate and is hauled to trestle above eight vertical kilns which utilize buckwheat anthracite fuel. Clinker is drawn, hand-picked, crushed to ¾-in., elevated, and deposited in three bins—one bin for the burned light-colored rock, one for the dark rock, and one for occasional needs. The clinker is next taken by an aerial tramway, to top of finishing plant. Tram buckets are loaded and unloaded automatically. Clinker is stored in three steel bins, then withdrawn, weighed, and fed to grinding mill. Pulverized product is air-collected into bin over final grinding tube-mill. Natural cement goes to four storage silos and

enroute to packers, it passes vibrating screens, the oversize returning to the finish tube-mill.—A. J. HOSKIN

Arkansas' only producing cement plant embodies simplicity and safety. W. E. TRAUFFER. *Pit and Quarry*, July 2, 1930, v. 20, No. 7, p. 35-46, 47 illustrations.—New plant of Arkansas Portland Cement Co. at Okay started operation last fall. Mill construction began in Nov., 1928. Crushing began June 18, 1929, and first shipment of finished cement was made Oct. 2, 1929, 125 carloads. There are only four principal pieces of machinery in the plant: a No. 60 swinghammer crusher, two Compeb mills, and 300-ft. rotary kiln. Raw materials are from bed of Austin chalk and overlying bed of argillaceous loam. Blasted rock and clay are hauled to plant in steel side-dump cars. Quarry-haulage system is merely temporary, and is, eventually, to be converted into electric, central-tower-control system. Single crusher can reduce from 35-in. to 1-in. Stone and clay are excavated on alternate days. Entire storage space is divided into four compartments with concrete walls. Gypsum is unloaded from box cars by power scraper to conveyor directly to storage. Silica sand, required to maintain correct SiO_2 content, is unloaded from gondola cars by same power scraper and conveyor. Rock, clay and sand discharge through plate feeder to pugmill. This, discharges to 3-compartment raw-grinding mill which uses steel balls, and resulting slurry is handled by pumps to any of six 400-bbl. concrete batch tanks, equipped with mechanical and air agitation. Slurry, in proper proportion, is pumped into concrete mixing tank, thence to slurry-storage tank, also equipped with mechanical and air agitator. Slurry moisture is maintained at 47 per cent. Kiln is 11½ ft. in diam. and 300 ft. long, and uses natural gas fuel. Slurry filter is being installed to increase kiln's capacity from 2,400 bbl. to 3,000 bbl. per day. Slurry cake will be discharged from filter to belt conveyor discharging to feeder, to kiln. Clinker drops from the kiln to steel dragchain, discharging to iron bucket elevator, that handles clinker to storage. Finish mill is 3-compartment, compeb mill with a peripheral screen and pick-up pipes between the first and second compartments. Ground cement is fed to pneumatic pumps by which cement is carried through 5-in. line to any of 12 storage silos, having total capacity of 230,000 bbl. Exbiners, screw conveyors and bucket elevators deliver cement to packhouse. Article gives details of power and transmission equipment, and describes laboratories, offices, shops and village with water supply and sewage disposal.—A. J. HOSKIN

PROPERTIES OF CONCRETE

Protecting reinforced concrete against corrosive solutions. HANS VÄTH. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 61, p. 1010-1, No. 62, p. 1026-8.—Foundation for a coke plant was built of aluminous cement (Alca) in contact with $CaSO_4$ soln. Above ground it began to deteriorate within 6 months. Test specimens proportioned 1:3, in water were in perfect shape and showed increased strength after 142 days, but specimens of mixes 1:6 and 1:10 suffered cracking and loss of strength. When placed in 10 per cent $MgSO_4$ soln. specimens of 1:3 and 1:6 seemed in good condition but were weaker after 131 days. The 1:10 specimens lost no strength, although they became white. When stored in ground water from the coke plant the 1:3 and 1:6 specimens appeared in good shape but lost strength, while the 1:10 deteriorated badly. When planted at the building a 1:5.7 specimen 4 by 4 by 22 in. bar cracked badly in 120 days. Similar specimens of high early strength portland and of slag cements were in good shape at end of same period.—F. O. ANDEREGG

The structure of mortar and concrete. "Der Aufbau des Moertels und des Betons." OTTO GRAF. 3rd edition, 1930, Julius Springer, Berlin W9 (Germany), R. M. 17.50. Reviewed in *Zement* (Germany), June, 1930, V. 19, No. 25, p. 596.—This enlarged edition deals with compressive strength, flexural strength, weather resistance, water permeability, shrinkage and expansion of cements and mortars. Special consideration is given to concrete made with volcanic slags and pumice. Experiments with mortars of different compositions are described. Directions are given for concrete control on the job.—A. E. BEITLICH

The concrete brick. "Der Betonwerkstein." 1930. Editor: Bund der Deutschen Betonwerke E. V. Berlin NW6 (Germany). Reviewed in *Zement* (Germany), June, 1930, V. 19, No. 24, p. 572—Properties of concrete bricks and their application in practice are described. Directions are given for their valuation.—A. E. BEITLICH

The yield of certain concrete mixes. A. G. DARWIN. *Concrete*, July, 1930, V. 37, No. 1, p. 29.—Since cement is usually most costly ingredient of concrete mix, it is desirable to so proportion aggregate constituents that for given required strength, range of workability and other factors, the minimum cement factor obtains. Following are some general conclusions that may be drawn from yield study of Moscow crushed basalt rock and Spokane sand concrete, but only under laboratory conditions. (1) For given water-cement ratios of 0.85, 0.90, and 0.95, yield decreases at nearly uniform rate with increase in dry-rodded proportion of sand to rock. (2) For given proportion of sand to rock by dry-rodded volumes, yield increases as water-cement ratio increases. (3) For a given proportion of sand to rock the yield increases as strength decreases.—C. BACHMANN

Miscellaneous concrete construction practices. K. GOSLICH. *Zement* (Germany), June, 1930, V. 19, No. 24, p. 567-8.—Disintegration of concrete is caused by water containing sulphuric acid or sulphates, especially the magnesium salt. New experiments seem to prove erroneous the conclusion that cements which are high in lime are more easily attacked by such waters. Most important factor is density of concrete which can be obtained by expensive rich mixtures or by carefully proportioned aggregates. Concrete pieces which are partly immersed in water show greatest corrosion at line between water and air. Capillarity of concrete and concentration of salts by evaporation are to blame for this effect. Paraffin and asphalt or mixtures of asphalt and tar are suggested for protection of concrete pipes.—A. E. BEITLICH

Solution phenomena of concrete. RICHARD GRUN. *Der Bauingenieur* (Germany), June, 1930, V. 11, No. 26, p. 451-4.—Solution of concrete can take place in two different ways, (1) by water which is poor in carbon dioxide by direct solution of lime, or (2) by water rich in carbon dioxide. In second case, lime is converted to calcium carbonate, then to soluble calcium bicarbonate and finally back to calcium carbonate which appears in voids and on surface of concrete. These reactions cause loss in strength and deterioration of concrete. Such action can be prevented by making dense concrete which does not allow penetration of water. Use of cement which is low in lime and addition of certain admixtures are suggested for concrete protection.—A. E. BEITLICH

Winter-laid 10,000-lb. concrete on Chicago viaduct. ARTHUR R. LORD. *Eng. News Record*, Aug. 14, 1930, V. 105, No. 7, p. 258. During the construction of new bascule bridge across Chicago River at Wabash Ave. in Chicago, a

large area of concrete deck slab and several supporting columns were removed from Wacker Drive. Chunks of concrete from the debris were sawed into 3x3-in. cubes for testing. Tests showed an average strength for cubes of 11,400 lb. per sq. in. Equivalent cylinder strength is considered to be about 85 per cent of this value. Cylinder tests at 28 days showed a strength of 2,620 lb. per sq. in. On this basis, strengths at 46 months are over three times those at 28 days, and over 2½ times those that would be expected at 28 days in summer weather for this mix and water-cement ratio. This concrete was made with seven sacks of cement, 14 cu. ft. of Beloit sand, and 22 cu. ft. of crushed limestone. Water-cement ratio was 6.5 gal. of water per sack of cement. During placing, the temperature of air above the slab varied from zero to slightly above freezing. All materials were heated to give temperatures in fresh concrete of about 80° F. at mixer, about 60° at forms and about 35° to 40° at upper surface of slab by the time it had hardened sufficiently for workmen to cover it with straw. Air beneath the slab, heated by salamanders, varied from 55° to 85° F. during curing period of seven days. Under the straw, temperatures at the surface of the slab were above 50° F. during the week.—D. E. LARSON

BRIDGES

International contest for construction of bridge over Lake Maelar in Stockholm (Sweden). *Zement* (Germany), July, 1930, V. 19, No. 30, p. 712-4.—First prize was given to plans by Prof. F. von Emperger, Vienna for reinforced concrete bridge consisting of two arches with span of 198 m. each. Roadway is 17.50 m. wide with two 2.25 m. wide sidewalks and consists of 5 cm. thick asphalt slabs. Dimensions of structure and details of reinforcements are given.—A. E. BEITLICH

Concrete arch Mississippi bridge at Minneapolis. *Eng. New Record*, July 10, 1930, V. 105, No. 2, p. 49-50.—Two reinforced-concrete rib-arch spans of 265½ ft. in the clear form the channel portion of the new Cedar Ave. bridge across Mississippi River at Minneapolis, Minn. They have rise of 90.5 ft. and are located on tangent of 611 ft., crossing river on skew. Three flanking arch spans on west side and two on east side are of 93 ft. span and are on curves of 5 deg. 41 min. and 5 deg. 18 min. respectively. All arch spans have two ribs 12 ft. wide and 24 ft. apart in clear, with thickness for main spans of 3.5 ft. at crown and 7.5 ft. at haunches. A three-center curve having radii of 154 and 48.5 ft. is used for intrados, and a curve having a single radius of 167.5 ft. is used for extrados. Each main span rib is reinforced with five steel ribs 31½ in. deep at crown. Chords are composed of pairs of angles 3½ x 3½ x ⅜ in. and web members of smaller angles. Each rib in side spans

is reinforced with sixteen longitudinal bars top and bottom tied together with loop bars 4 ft. apart. Footings for three river piers are 30 x 54 ft. At east and center piers they rest on sandstone bedrock while west pier footings are supported on 180 piles 32 to 42 ft. long driven into gravel formations and spaced 3 ft. c. to c. both ways. Transverse spandrel walls practically full width of arch ribs, and spaced 13 ft. 4½ in. c. to c. in the main spans and 12 ft. in the flanking spans, have cantilever brackets for sidewalls and carry pairs of transverse 24-in. I-beams which support 12-in. reinforced-concrete deck slabs.—D. E. LARSON

Design of road bridges. C. S. CHETTOE. *Roads and Rd. Constr.* (England), June 2, 1930, V. 8, No. 90, p. 181.—Culverts. Except where there are rock foundations, culverts usually have inverts. Total foundation pressure is equal to vertical component of forces acting on culvert top, plus weight of culvert and if necessary, water, when it is running full. On mass concrete or rock foundation, pressure would be either concentrated under walls, or distributed along whole base, with maximum at centre, according to whether moments due to forces caused convexity or concavity upwards, in invert. On yielding clay, pressure tends to become uniform for all conditions of loading. Culvert is designed as two fixed elastic arches with abutments at centre of top and invert, where no angular displacement is assumed. Horizontal thrust on invert is equal to actual forces on one side of culvert less horizontal thrust at crown. Shear at sharp bends may be appreciable. Ideal shape is a circle. No allowance need be made for temperature shrinkage, or rib shortening. Formulae are given for the necessary bending moments. Rectangular culvert is most suitable for spans up to 8 or 10 ft. on account of simplicity of shuttering and steel fixing, although it is not most economical shape for material. Large culverts are usually semi-elliptical with straight or slightly rounded inverts, and sometimes, extended invert ends. For culverts passing beneath deep bank, on compressible soil, special longitudinal reinforcement may be required either in deck and invert, or at four corners, to take up positive bending moments. Vertical reinforcement may need to be increased to take shear.—JOHN E. ADAMS

Design of road bridges. C. S. CHETTOE. *Roads and Rd. Constr.* (England), July 1, 1930, V. 8, No. 91, p. 217.—Abutments: If filling is not to be completed until after decking is in position, final stresses only need be considered; otherwise abutment wall should be designed to act as retaining wall during construction, and to take final live and dead loads in addition. Downward forces on abutment are weight W' and reaction from girders, W''. The horizontal forces will be P, due to earth pressure and surcharge and $\pm W''$ x m, where m is the coefficient of friction between girder and bearing plate. Abutments should be able to withstand any movement due to lengthening or shortening of girders. Mass concrete girders should have thickness of 0.35 x height at base and be relatively thicker at top than ordinary retaining walls. For spans up to 20 ft. rolled steel joists are allowed to rest directly on smooth concrete without provision for expansion. Bearing plates are usually provided for built-up girders, up to 40 ft., girders from 40 to 60 ft. span usually are carried on cast iron or steel plain bearings arranged for sliding at one. When rein. conc. girders are used no expansion bearings are necessary up to 35 ft. span, particularly if carried on piles. Spans up to 50 ft. may have felt bearings, while larger spans have two outer and two inner plates of steel and copper respectively. In lighter, reinforced concrete abutments having counterforts and sill beams, which take the decking beams, the wall prevents sill beams from deflecting and taking much of load. Curtain walls which span horizontally, are designed for moments of $\frac{pl^2}{12}$ at counterforts, and $\frac{pl^2}{24}$ at mid

span. The end spans are designed for $\frac{pl^2}{10}$. Distribution steel must be provided at sill and junction with foundation, to avoid cracks due to reverse moments. Counterforts are designed as ordinary retaining walls and should be checked for safety before and after decking is on, and for full live loads. For arch abutments, of mass concrete, final thrust should approximately bisect bearing surface and be normal to it. The top of arch abutment must never be finished off horizontally or it will have no shear resistance. Abutments may be cellular with a sill beam. Active earth pressure, only, is allowed for except where abutments are carried against hard virgin soil, or rock. In poor ground, short cantilevered end-spans are economical. Piers: In case of adjacent arch spans, resultant thrust at base should lie within middle third, worst case being when one span is fully loaded, and other unloaded. If A is free horizontal deflection due to maximum difference of horizontal thrust at pier top, and B horizontal movement of springings if free to slide on pier top, due to the same force, then the horizontal force taken by pier will be approximately $\frac{B}{A+B}$ and the rest will be taken by the arches.—JOHN E. ADAMS

Exhibition of new concrete bridges built in Bavaria (Germany). A. ZENNS. *Zement* (Germany), July, 1930, V. 19, No. 28, p. 660-3.—Design and construction of a number of reinforced concrete arch-, frame- and girder-bridges are shown by several photographs and drawings.—A. E. BEITLICH

Arch bridge near Echelsbach (Germany). (See FIELD CONSTRUCTION —Bridges.)

BUILDINGS

Tables for construction technique. "Bautechnische Tabellen." KARL-JOHANN HOCHREUTER. 1930, Gustav Winters, Bremen (Germany). Reviewed in *Zement* (Germany), July, 1930, V. 19, No. 30, p. 714.—Book contains tables for mathematical calculations of static and dynamic stresses in steel and reinforced concrete construction. Directions for erection of such structures are given. Tables are valuable aid to contractor and designer.—A. E. BEITLICH

Warehouse in Minden (Germany). *Zement* (Germany), June, 1930, V. 19, No. 23, p. 538-9.—A storage house with a capacity of 6000 tons wheat was built in reinforced concrete skeleton construction. Four floors, designed for live load of 2000 kg./m², were constructed with slab-girders. Eight bins, 13 m. high and 3.80 m. x 2.60 m. wide, are on north side. Grain elevators, mill equipment and offices are located in building.—A. E. BEITLICH

Tests on concrete frames simulate effects of earthquake action on buildings. *Eng. News Record*, July 10, 1930, V. 105, No. 2, p. 55.—This article, which is an abstract of paper read before recent international engineering congress in Japan by Mikishi Abe, consulting engineer of Tokyo, presents conclusions from tests made to study action of rectangular reinforced concrete frames under repeated horizontal load. In these tests, made at University of Illinois, periods of free or natural vibration of reinforced concrete frames were measured in order to compare them with known formulas. Four main points considered were: (1) Behavior of frames under horizontal loads repeated many thousand times. (2) Free vibration periods before and after cracking of frames. (3) Effect of construction joints upon horizontal deflection under repeated static horizontal loads. (4) Methods of improvement in design and construction. Mr. Abe stated that the results were in fair agreement with the analyses. Several of his conclusions are summarized as follows: (1) Observed stresses in frames were not increased by

repeated application at low loads. Under high loads, stresses were slightly increased, but intensity was well within computed values. (2) Periods of free vibration of test frames, measured by aid of motion photographs, were about 0.03 second, before any cracks had developed. After cracks had developed, periods were about 0.04 second. From these results, it is argued that there is small possibility of synchronizing natural vibrations of a building with vibrations of a great earthquake after the composing members have been cracked. (3) Horizontal deflections of frame with ordinary construction joints at feet of columns were almost equal to those of frame with no such joints, but were much larger than where dowels were used. (4) Use of large haunches at end of beam was apparently inadvisable because many small cracks appeared in haunches. Bending stresses at top of the column were much reduced, while stress at bottom was not reduced by use of large haunches. (5) Construction joint in beam is not objectionable if properly built although cracks due to vibration tend to follow joint.—D. E. LARSON

Design and construction of modern factory in reinforced concrete. A. W. LEGAT. *Structural Engineer* (England). May, 1930, V. 8, No. 5, p. 178-190.—Soap factory requiring 4066 cu. yds. of concrete is described in detail from selection of site and general dimensions to details of design, materials, and methods of construction. Building features reinforced concrete loading bays, milling bay including hoppers, and in general reinforced concrete for the entire building with two exceptions, first, where steel was used for roof trusses and materials storage tanks, and second, where brick was employed for sleeper walls and temporary end paneling.—V. P. JENSEN

New structures of paper plant in Scheufelen near Oberlenningen i. Wuert. (Germany). A. WEGENAST. *Zement* (Germany), June, 1930, V. 19, No. 24, p. 565-7.—Several new buildings were erected in enlarging program of big paper plant. One building which serves as connecting link between old buildings is 23.65 m. long, 11.75 m. wide and 31 m. high. It contains main stairway, washrooms and several rooms for general purposes. Entire building and stairway is constructed of reinforced concrete. Main building, which houses machinery and material storage is 5-story structure with two rows of center columns spaced 5.50 m. apart. Connecting beams have span of 7.50 and 9.65 m. High early strength portland cement was used for their construction. Ceilings are "Remy" ceilings designed for live load of 1000 kg./m.^{2} Third building shows interesting ceiling construction. Area of 2960 m^2 is covered with only eight columns. High quality iron-portland cement was used. Transformer building is 49.50 m. long, 6.00 m. wide and 4.30 m. high.—A. E. BEITLICH

DAM

Cobble Mountain dam of Springfield, Mass. JAMES B. PORTER. *Eng. and Con.*, July, 1930, p. 255-257.—Highest hydraulic fill dam in the world will make use of concrete cut-off walls in bottom of dam. These walls extend up slopes on each side. Concrete arched wall 14 ft. wide on top, with vertical upstream face and ¼ to 1 downstream face, and with 100 ft. radius is to be at downstream toe of hydraulic fill dam. Spillway will care for 400 second feet per square mile of watershed. Reinforced concrete arch bridge will be built over spillway and will carry highway that goes over top of dam.—N. H. ROY

MISCELLANEOUS

Reinforced concrete design simplified. JAMES R. GRIFFITH. *Concrete.* June, 1930, p. 45-47.—Design of long columns, h/R greater than 50, according to A. C. I. specifications is greatly simplified by use of a nomographic chart containing all necessary quantities.—N. H. ROY

Reinforced concrete design simplified. JAMES R. GRIFFITH. *Concrete*, July, 1930, V. 37, No. 1, p. 43-46.—Prof. Griffith has constructed charts to simplify design of tied columns according to A. C. I. Code. Three quantities are given in charts, area of longitudinal steel, total column load, and size of square columns for 2000 and 3000 pound concrete. Comparison is made with Joint Committee requirements. A. C. I. Code is the more liberal of the two. —N. H. ROY

Method of calculating strength of steel beams encased in concrete. O. H. MENGERING. *Concrete*, June, 1930, V. 36, No. 6, pp. 35-37.—Rational method of analysis of composite steel and concrete beam sections is presented. Author gives methods of obtaining areas and statical moments and location of neutral axis of compound sections. Expressions for K, kd, and b, width of member, are set up for balanced section. Sufficient material, concrete or steel, is supplied to balance tensile steel area. Expressions for moments of inertia of compound and balanced sections are also given. Likewise equations for moment of inertia and width of stem of tee-beams are given. Shear, bond, deflections and resisting moments are discussed and typical problems solved. Width of beams is found to vary with grade of concrete and is inversely proportional to value of n, ratio of moduli of elasticity of steel and concrete. For the section chosen, the resisting moment was increased about 13 per cent by encasing in concrete. The center deflection of simply supported beam of the section used was from 36 to 27.5 per cent less for the concrete encased beam than for steel section alone.—N. H. ROY

Shrinkage of concrete as a factor in compressive steel stress. *Eng. and Con.*, June, 1930, p. 234-236.—Prof. Maney's discussion and conclusions, as presented to Western Society of Engineers April 7, are summarized and two general conclusions drawn regarding tremendous increase in compressive steel stress in a beam under sustained loading over period of two months. Plastic flow is negligible factor. Shrinkage is controlling factor. Amount and effect of shrinkage are predictable. A law regarding shrinkage has been evaluated for benefit of designers. Amount of shrinkage was found to be controlled by percentage by volume of cement paste and quality or water-cement ratio of paste. Data from experiments is given partly by curves. Measured stresses in compressive steel after 40 days of continuous loading were found to be approximately 2½ times the calculated stresses. Deformations in concrete at compressive surface were very high. Flow of concrete around reinforcing rods took place without damage to bond. A. C. I. Column Code and possibilities for its improvement are discussed at length. Specifications nf_c for compressive steel holds only for load changes; for time loading it is not sufficient. For ordinary case nf_c is only a small part of total compressive steel stress. It is predicted that compressive steel with high elastic limit and controlled shrinkage will feature changes about to take place in reinforced-concrete design.—N. H. ROY

Steel beams much stronger when encased in concrete. F. A. RANDALL. (Report of Committee of the Western Society of Engineers), *Concrete*, June, 1930, V. 36, No. 6, p. 34.—Tests made at plant of American Bridge Co., at Gary, Indiana, on floor framing encased in concrete, were completed and reported upon on May 12. Floor system was described in *Concrete*, Nov., 1929, p. 24. Deflections and deformations were measured on steel members, which were then encased in concrete and readings taken again after 28 days. Loads up to twice dead plus design live loads were applied. Test results were compared with usual design computations. Tensile stress in bottom flange of steel beams was greater than compressive stress in upper flange, due to concrete in upper part of member taking compressive stress,

whereas concrete in lower part of member probably did not take any tensile stress. Thus neutral axis of composite member was in effect raised and tensile stress was lower than it would have been in an unencased member. Measured stresses in tension flanges of fully loaded beams averaged 56 per cent of so-called computed stresses for cinder concrete panels and 57 per cent for gravel concrete panels. "Computed stress" denotes theoretical stress obtained by usual design methods, considering that steel section carries entire load. Committee recommends working stress of 24,000 lbs. per sq. in. be allowed on steel section when it is encased in manner similar to that of tests and using materials of like quality on I-beams and girders up to 24 in. in depth. Full committee report is contained in the June Journal of the Western Society of Engineers.—N. H. ROY

The steel requirement for reinforced concrete beams. KURT BERNHARD. *Zement* (Germany), June-July, 1930, V. 19, No. 25, 27, 28, 29, p. 591-5, 637-40, 663-6, 688-90.—Author illustrates influence of "steel-coefficient" for calculation of reinforced concrete beams as this was done for concrete slabs in previous article (*Zement* (Germany), April-May, 1930, V. 19, No. 16-20, p. 379-83, 405-9, 447-52, 474-8). Examples of practice showing steel requirements under all possible conditions of stresses are cited. Formulas and calculations are given for single beams and panel construction.—A. E. BEITLICH

Water power stations. "Wasserkraftanlagen." FELIX BUNDSCHU. 1929, 130 pp. Walter de Gruyter, Berlin, R. M. 3.00. Reviewed in *Zeitschrift des oesterreichischen Ingenieur und Architekten Vereins* (Austria), April, 1930, V. 82, No. 17-18, p. 156.—Book gives (1) general directions for design and construction of water power stations, (2) describes locks and breakwater and (3) water pressure pipe construction and laying.—A. E. BEITLICH

Calculation of masses in reinforced concrete construction on theoretical basis. "Die Massenberechnung im Eisenbetonbau auf theoretischer Grundlage." FRITZ BUECHI. 1929, 139 pp. Wilhelm Ernst und Sohn, Berlin, R. M. 5.60. Reviewed in *Zeitschrift des oesterreichischen Ingenieur und Architekten Vereins* (Austria), May, 1930, V. 82, No. 21-22, p. 188.—Book discusses analyses of calculations for masses in concrete construction and gives formulas for calculation of all kinds of cross-sections. Several examples of practice are cited and numerous tables are given.—A. E. BEITLICH

Pile driving calculations with notes on driving forces and ground resistance. A. HILEY. *Structural Engineer* (England). July, 1930, Vol. 8, No. 7, p. 246-259 and August, 1930, V. 8, No. 8, p. 278-288.—A comprehensive treatment of pile driving calculations giving both theoretical analyses and experimental data for various soil conditions, types of hammer, and types of pile.—V. P. JENSEN

Experimental structural engineering. H. W. COULTAS. *Structural Engineer* (England), August, 1930, V. 8, No. 8, p. 290-301.—Theoretical discussion includes an historical review bringing out laws of general work and virtual work, Mohr's equations, and Maxwell's theorem of reciprocal deflections. Solution of indeterminate structures by means of models is described and Professor Begg's method and apparatus are discussed in detail.—V. P. JENSEN

Design of River Des Peres drainage channel, St. Louis, Mo. W. W. HORNER. *Eng. News Record*, July 24, 1930, V. 105, No. 4, p. 124-128.—Four of 13 miles of River des Peres Drainage Canal now under construction in St. Louis, Mo., will consist of reinforced concrete arch conduit. Of this

amount, 10,000 ft. will consist of twin arches each 29 ft. wide and remainder of single arches 32 ft. wide. In designing the arches, stress analyses were made for both completely fixed and completely hinged end conditions and the actual detailing was on the basis of stresses less than maximum in either case. Sections were designed for earth backfills of 5, 10, 15, and 20 ft. over the crown, and for three different bearing values under footings. Specified working stresses were 800 lb. per sq. in. for concrete and 20,000 lb. per sq. in for steel. Six sacks of cement were used for each cu. yd. with not more than 55 lb. of total water per sack of cement. Aggregates were varied to secure most workable concrete consistent with good practice. Materials were measured by weight and mixing time of 1½ minutes was required. Steel forms were specified and were required to remain in place until concrete had attained compressive strength of at least 1,200 lb. per sq. in. To determine this strength, cylinders were cast at time of pouring and cured under conditions similar to those of concrete in forms.—D. E. LARSON

Dock and harbor construction in British colonies. MAJOR JOHNSTONE-TAYLOR. *Concrete*, July, 1930, V. 37, No. 1, p. 23.—These notes are principally concerned with the use of reinforced concrete as an alternative to timber for jetty and bank protection work in a British Colonial development in Asiatic waters. On Whang Poo River, Shanghai, there are comprehensive works consisting of reinforced concrete skeleton wharf supported on piles of same material and reinforced concrete quay wall of buttressed class forming part of same works. Wharf is 174 ft. wide and 1160 ft. long. Piers are 15 in. square and spaced 15 ft. apart in each direction. Each pile in turn is supported on a group of 14 in. square piles. Beams run across the wharf from side to side over each row of piers and they support a system of cross beams spaced 5 ft. on centers. Bases of piers which are pile caps are connected both ways by horizontal members. Piles were molded in a horizontal position. Driving was effected without use of a steel helmet. A thin piece of pine was placed directly on the pile head, above which was a ¾ in. steel plate surmounted by 4 in. of hardwood. Arrangements were made for the pile to run in guides between rubber covered rollers packed with thin pine battens.—C. BACHMANN

Nomogram for calculating columns without spiral reinforcing (Axial load). JORGE QUIJANA. *Ingenieria* (Mexico), Feb., 1930, p. 57.—A simple alignment or nomographic chart, one of a series of such charts, for use in reinforced concrete design and investigation, solving the relation $P = [A_c + (n - 1)A_s] f_c$. Left hand scale or line A_c, middle scale P and right hand scale A_s. Explanation of the use is given on the chart. All in metric units.—MILES N. CLAIR and C. G. CLAIR

Nomogram for calculating columns reinforced longitudinally and with spiral reinforcing. JORGE QUIJANO *Ingenieria* (Mexico), Feb., 1930, p. 73.—A simple alignment or nomographic chart, one of a series of such charts for use in reinforced concrete design and investigation, solving the relation $P = A_c f_c + n f_c p A$. Left hand scale or line D or column diameter, middle scale P, and right hand scale p. Explanation of use is given on the chart. All in metric units.—MILES N. CLAIR and C. G. CLAIR

ARCHITECTURAL DESIGN

Modern church structures by Prof. Dominikus Boehm. A. HOFF. *Zement* (Germany), July, 1930, V. 19, No. 27, p. 640-1.—Several church constructions by one of the leading German architects are described. Modern church design differs very much from earlier methods. Vaults of great spans are desired which can be made of reinforced concrete. Arch construction without centerings were used by architect in building new church in Neu-

Ulm (Germany). Excellent acoustical and light effects were obtained in this structure. Similar designs were used in construction of churches in Gross-Welzheim and Frielingsdorf where special decorative window construction provides indirect light. Mass concrete is being used for convent in Muenchen-Gladbach. Finish of surface adds to strong effects. Concrete is more suited than any other material to produce architectonical effects in modern church construction.—A. E. BEITLICH

New Concrete filteration plant. FREDERICK COLEMAN. *Architect Building News* (England), May 9, 1930, V. 123, No. 3203, p. 35.—The new concrete filtration plant of Metropolitan Water Board at Kempton, England, is a splendid example of artistic possibilities provided by massing of concrete. This ferro-concrete building is a monolith: column and beam, arch and wall become *one* stone, in which connecting steel rods link the most distant parts together. The possibilities of texture, of color inhering in the product make it a thing through which the designer can make his feelings flow. The more a building tends toward a mono-material building, the more nearly will perfect style reward an organic plan and ease of execution economize results. The more logical will the whole become. In all real art, structure and design form an inseparable unity. . . . The problem is to express in beautiful forms the type of construction thrust upon us by a utilitarian age.—REXFORD NEWCOMB

Concrete. DR. ERICH MENDELSOHN. *Architect Building News*, (England), May 23, 1930, V. 113, No. 3205, p. 671-72.—The pliability of concrete leads many an architect to continue in his old habits with the new material, and not only as regards architectural style, but also in his building technique. But to build in concrete involves a revolution in building technique. We build frames—that is, we concentrate the load on single points instead of distributing it over the wall as a whole. We pour in concrete instead of, as formerly, setting the single parts, bricks or stones, on top of each other. We assemble a building like a machine; mechanical accuracy replaces the skill of craftsmen and his individual subtleties. For our buildings we require elevators and spouting towers instead of mason's guilds and scaffolding; we calculate exactly beforehand every detail of the construction; we organize on a large scale instead of being contented with empirical attempts and occasional lucky results. This fundamental alteration in the methods of building is one of the causes of change in ideas on architectural form. The success of the new material consequently give the architect entirely new creative possibilities. The second quality of the new materials, steel and concrete, that of being able to live a life of their own, to exist as absolutely independent materials, gives the lie to those architects who see in them only an additional means of realizing dreams born of their excursions into a mummified past. We rejoice in the new materials because they impose on us obligations which, if we accept, set us free for new and original creations. We know that constructions in steel and reinforced concrete are very difficult to alter. That is why we consider the plan of the building as though it were a living being. We carefully avoid anything in the nature of a schematic design, because each plan has its own life, its own purpose, its own conditions of movement and transport, its own unique form. We reckon with it and with its form as something determined by its nature—and thus harmonize calculation and form, industrial purpose and architectural form. We settle in advance the sequence of separate parts of the building; we determine its rhythm, which is of more value to us than any decorative trimmings. We see in constructing a creative activity; in the creative construction, an architectural work of art. With our girders we span the greatest spaces. We light them by great glass surfaces between the elastic supports. By means of glass we get rid of inert matter and make the building light and transparent. We transfer the principles of bridge construction to building and by means of cantilevers raise certain parts above the earth, and cause them to float in the air.—REXFORD NEWCOMB

Lincoln Cathedral repairs. *Architect Building News* (England), April 18, 1930, V. 113, No. 3200, p. 499.—The reparation of Lincoln Cathedral has so far proceeded that the interior of the nave is at last freed from scaffoldings. The reinforced concrete ties, holding in the west front which was in danger of falling outwards, have been completed; as also, similar reinforcements to prevent the future spreading of the arches under central tower, and the buckling of the nave walls.—REXFORD NEWCOMB

Concrete church Jacobi in Stettin (Germany). (See FIELD CONSTRUCTION—Buildings.)

FIELD CONSTRUCTION

BRIDGES

Bridge over river Allien in Langeac (France). FRITZ EMPERGER. *Zement* (Germany), June, 1930, V. 19, No. 23, p. 537-8.—From spring 1927 to spring 1929 this reinforced concrete highway bridge was built. River is 2 m. deep and 20 m. wide during greater part of year, but rises about 6 m. and is about 140 m. wide during high water periods. Total structure is 140 m. long and consists of two concrete arches carried on two shore abutments and one river pier. Bridge crosses river at approximate angle of 71 degrees. Span of each arch is 68 m. and their height is 13.6 m. Arch ribs are 0.60 m. wide and from 1.20 m. to 1.60 m. high. Roadway is 5.20 m. wide and has two sidewalks for pedestrians 1.10 m. wide on each side. Floor system shows normal design; it is suspended from the arches. Concrete floor slabs are covered with layer of asphalt. One centering was used for both arches since they have same dimensions. Difficulties were encountered in making foundations for river pier.—A. E. BEITLICH

Arrangement and preparation of structural materials for construction of bridge over river Ammer near Echelsbach (Germany). FERDINAND DUELL. *Die Bautechnik* (Germany), Jan., 1930, V. 8, No. 1 and 4, p. 9-15, 52-5.—Aggregates were found in 4 km. distance from site of construction. Gravel, which had high loam content was washed in special plant. Water was pumped 80 m. high from river with high pressure pump which delivered 8 cu. meter of water per hour through pipe (52 mm. in diameter) to tank of 10 cu. meter capacity. Sand was transported by truck to storage bins. Aerial tramway carried materials to opposite side of river. Two concrete mixers of 350 and 500 liter capacity were used. Cement silo had room for 25 carloads. Laboratory for testing cement and concrete was erected near site. Distribution and placing of concrete during all stages of construction are described. (cf. *Der Bauingenieur* (Germany), June 1930, V. 11, No. 23, p. 391-406.)—A. E. BEITLICH

Reinforcing of bridge over the river Roeder between Goerlitz and Dresden (Germany). FRITZSCHE. *Die Bautechnik* (Germany), Jan., 1930, V. 8, No. 2, p. 25-31.—Old railway bridge which was badly damaged by action of water and weather was widened and provided with new reinforced concrete supports. Interesting construction methods were used for connection of old and new structure. High early strength cement was used which gave compressive strength of 330 to 380 kg./cm.^{2} after three days.—A. E. BEITLICH

Bridge over river Breitach near Riezlern (Austria). E. MUELLER. *Die Bautechnik* (Germany), Jan., 1930, V. 8, No. 3, p. 33-5.—Highway bridge over deep valley of Breitach in Austrian Alps is three hinged arch bridge of reinforced concrete. Structure consists of three parallel arches of rectangular cross-section. Span is 51 m. and its height 13 m. Roadway is supported by

eleven vertical reinforced concrete frames, six of them resting on arches, rest being placed on special foundations on both shores. Openings between frames are 5.50 m. Arches are 1.10 m. high at abutments and 0.65 m. at centers; their width is 0.70 m. Cross-sections of columns vary from 30 by 30 to 40 by 40 cm. Roadway is 5.00 m. wide with two 1.00 m. wide sidewalks on both sides. Special construction of abutments was necessary. Detailed description of reinforcements is given. High early strength cement was used for greater part of structure. Compressive strength after 6 weeks was 250 kg./cm.^{2} Foundations were made from ordinary portland cement. Scaffolding and formwork consumed much labor since high water is very frequent. Two wooden towers, 15.6 and 16.9 m. high with pile foundation supported formwork for arches. Materials were mixed in one mixer on right shore. For one cu. meter aggregates 280 kg. portland cement was used. Dump cars transported concrete to big chute.—A. E. BEITLICH

Arch bridge near Echelsbach (Germany). H. SPANGENBERG. *Der Bauingenieur* (Germany), June, 1930, V. 11, No. 23, p. 391-406.—Highway bridge over river Ammer with span of 130 m., which is longest span bridge in Germany, was opened for traffic in December 1929 after one year of construction. Bridge makes short cut and eliminates long detour of important highway. System Melan-Sachsenberg was used for construction of two halves of arch which were built without centerings. Gravel load of weight of concrete was placed upon free ends of arches to keep stresses constant. Load was decreased in same rate as construction progressed. Bridge consists of two hollow box-shaped arches of 130 m. span, placed in 6 m. distance. Ten I-beams and two U-beams at abutments connect both arches. Ribs have constant width of 1.50 m., their height increases from 2.00 m. to 3.20 m. Walls of ribs are 35 cm. thick and are stiffened by inner partitions. Abutments are 11 m. wide. Roadway, which is 8.30 m. wide, rests on 14 vertical frames of different height supported by arches. Distance between frames is 10.50 m. Their dimensions increase with their length, greatest being 1.1 m. by 0.8 m. by 24 m. Two main girders of roadway are 1.10 m. high and 0.4 m. wide with distance of 6 m. Roadslabs are 20 cm. thick and are cross reinforced. Four expansion joints were made. Detailed description of steel structure is given. Special care was necessary for closing of arches in center of bridge. Author gives discussion of reasons why box-shaped cross section of arch ribs was selected. He also gives calculations of static and dynamic pressures and stresses which occur in structure. Forms were made at site in small sections and were raised to iron structure. Two suspended platforms could be moved along inner part of arches. Aggregates were found in neighborhood and furnished very good construction material after being washed. Mixture of 40 per cent sand and 60 per cent gravel of 25 mm. size with 340 kg. cement was used for one cu. meter of concrete. Compressive strength after 28 days was 390 kg./cm.^{2} Concreting was done without any difficulties. Concrete was transported in buckets for lower parts of arch and was poured through chutes in center part. Compressed air hammers provided dense concrete. For 14 days after pouring, concrete was wetted three times per day to prevent early shrinkage. Article is accompanied by 32 illustrations.—A. E. BEITLICH

The collapse of the bridge over the river Oder near Gartz (Germany). GUSTAV HAEGERMANN. *Zement* (Germany), May, 1930, V. 19, No. 21 and 22, p. 494-7, 517-21.—Bridge was three-hinged arch which rested on two pillars in river and two abutments on land. Entire structure was made of reinforced concrete. Distance between pillars was 58.2 m. and between pillars and abutments 37.7 m. each. Height of middle arch was 10.5 m.; side arches were 7.5 m. high. Width of street was 5 m. Collapse was caused by crumbling of one of pillars. Dimensions of pillars was 11.30 m. long and 3 m. wide. Construction was nearly finished and removal of wooden planks was started, when

pillar collapsed. Middle arch fell into river and broke. One of side arches was pushed 1 m. over abutment, breaking latter, but was not damaged. This proved the good quality of reinforced concrete. Samples of pillar were taken and some of them were very soft. Calculations of chemical analysis showed that approximately 20 per cent of cement had leaked out on account of heavy motion of water. Pillars were constructed by "under-water-casting" method with concrete of 1:6 mix. Heavy steel piles were driven 15.7 m. below water level and excavation was made 12.1 m. deep. Forms consisted of 1 in. planks with 0.5 cm. wide joints. Height was 8.8 m.; foundation was 13.20 m. long and 5.5 m. wide. Concrete mixer and distributing arrangement was placed on top of foundation. During pouring of concrete an excess of water forced its way into the excavation, which prevented part of concrete from hardening and caused separation of concrete components.—A. E. BEITLICH

Winter-laid 10,000-lb. concrete on Chicago viaduct. (See PROPERTIES OF CONCRETE).

BUILDINGS

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, June, 1930, V. 36, No. 6, p. 38.—Principal feature in form work for drop panel around column head in flat-slab construction consists of square panel or platform that forms bottom of concrete drop panel. Form work for drop panel is supported in much same way as floor slab, namely, by a framework of joists and girts which in turn are supported by 3 x 4 in. or 4 x 4 in. centering posts. Two girts (one along each side of drop panel) furnish entire support for drop panel form. After panel is set in place its sides are closed with dressed 2-in. pieces whose dressed height is distance between bottom of finished concrete drop panel and finished floor slab, less $\frac{7}{8}$ in. A $\frac{7}{8}$-in. fillet is then tacked all around top of drop. Stripping of form work of the drop panel must be done in connection with stripping of rest of floor bay, as follows: (1) Assuming that "permanent" shores have been placed under surrounding floor bays and that metal forms of column capitals have been removed, loosen wedges between girts and tops of centering posts, but do not completely remove the wedges. (2) Remove two joists on one side of column by sliding them out of hangers, and let down that half of form panel. (3) Repeat foregoing operation on other side of column. (4) Remove double-headed nails from scabs. (5) Remove the 1 x 6 in. horizontal pieces that brace the centering posts, and take posts down.—C. BACHMANN

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, July, 1930, V. 37, No. 1, p. 38.—Present article deals with form work for walls above grade. They may be ordinary exterior or interior bearing walls; or they may be curtain walls extending between pilasters, supported on their own footings but carrying nothing except their own weight; or they may be supported by pilasters and have no footings. Use of 30-in. wall form units employed in foundation wall construction is not usually advisable above grade. Better workmanship is obtained if form panels are built to size of entire wall panel, extending from pilaster to pilaster and from floor to floor. Inside panel extends from completed floor or other support to underside of form boards for floor above. Height of outside panel will depend on position of belt courses or similar details. Best type of waling strip consists of two 2 x 6 in. timbers spiked together through fillers of 1 x 6 in. material, about 3 ft. apart. Space should be found to build wall form panels for first story in a lying-down position alongside place where they are to be erected. Waling strips are laid down, vertical studs tacked to them with double-headed nails, and form boards are nailed to studs. Panels are then raised from both sides, joined with column or pilaster forms and tie bolts and concrete or wooden

spreaders placed and tightened. False frames for windows and other openings are set against outside panel before inside panel is raised. Form work for wall pilasters is erected independently in manner previously described. Pilaster form work should be erected and thoroughly braced before wall form panels are raised into position to provide secure anchorage for latter.—C. BACHMANN

New Herrentor high school in Emden (Germany). HIRT. *Zement* (Germany), July, 1930, V. 19, No. 31, p. 733-4.—Building covers area of 2940 m^2 and rests on foundation consisting of 1460 wooden piles 11 m. long. Floor construction in reinforced concrete is of interest. Arrangement of reinforcements is described.—A. E. BEITLICH

Construction of building corner in reinforced concrete. THOMAS. *Zement* (Germany), June, 1930, V. 19, No. 26, p. 616-7.—Corner of building which was hindrance for traffic in narrow street, was removed and upper stories of building supported by interesting reinforced concrete construction. —A. E. BEITLICH

Concrete church Jacobi in Stettin (Germany). K. DAHL. *Zement* (Germany), July, 1930, V. 19, No. 29, p. 681-2.—Formwork, placing of reinforcements, concreting and removing of forms for church construction was carried out within 9 weeks. Six concrete frames, spaced 5.0 m. apart, support structure. Inner ceiling is made of wood in order to improve acoustics.—A. E. BEITLICH

High school construction in Kassel (Germany). WILHELM DAVID. *Zement* (Germany), June, 1930, V. 19, No. 26, p. 610-3.—Difficulties were encountered in placing foundations. Ground consisted of loose filled material to a depth of 8 m. Numerous single foundations were made on which 4-story building rests. It is 25 m. long, 15 m. wide and 9 m. high. Roof is of reinforced concrete. Several side-buildings show interesting construction.—A. E. BEITLICH

Design and construction of modern factory in reinforced concrete. (See ENGINEERING DESIGN—Buildings.)

DAMS

Water power works at river Shannon in Ireland. M. ENZWEILER. *Die Bautechnik* (Germany), June, 1930, V. 8, No. 25, p. 359-70.—Shannon river is being dammed about 16 km. upstream of Limerick near village of O'Briensbridge. Water canal of 12 km. length with capacity of 600 cu. meters of water per second connects dam and power station. Difference in water levels of 30 m. is utilized in one stem for production of 90,000 kw. with three Francis-turbines of 38,600 H. P. each. Dam is of overflow principle and has two openings of 18 m. each with rigid crests. Four openings at base are 10 m. wide. Interesting feature of dam is construction of canal for passage of fish. It is made of concrete in 16 steps, each step being 50 cm. high, at left side of dam. Dam of intake canal is of similar design. It is founded on sandstone rock and has three openings of 25 m. and one 10 m. wide passageway for ships. Total structure is 97 m. wide between shore abutments. Upper part of openings is closed by one continuous gate which extends over all three openings with total length of 90 m. It is 5.40 m. high and 2.50 m. wide and consumed 620 cu. meters of reinforced concrete for its construction. Cross section of gate is box-shaped with two horizontal inner walls. Outer walls are 27 cm., bottom and floor are 40 cm. and inner walls are 28 cm. thick. Difficulties were encountered during construction of water canal, which leads to power station. Climatic conditions were very unfavorable with heavy rainfalls. During three and a half years of construction period a total of 7 million cu. meters of

ground and one million cu. meters of rock were moved. Three reinforced concrete bridges, two of them being three-hinged arch bridges, were built over canal. Power house rests on limestone rock and is entirely built of concrete. It consists of three sections, one of which is generating room for three turbine-driven generating units; other sections are for switchboards and transformers. Station is designed for later enlargement with total of 6 turbines. Water lock at end of water canal is of interesting design. Its foundations are placed on limestone rock. For construction of this 95.50 m. long structure were used 40,000 cu. meters of concrete. It is 27 m. high. Expansion joints were placed in 30 m. distance of each other; they are sealed with copper strips which are embedded in bitumen. Lock has six openings, three of which are connected with 6 m. wide pressure pipes. Centers of water pipes are spaced 15 m. apart. Special shaped concrete walls are placed in front of openings. Pipes between water lock and power house are 44 m. long each and are supported at three places. Opening of 5 m. is in water lock as passage for water when turbines are not in use. Article is completed by 38 illustrations and graphs, showing construction in all phases.—A. E. Beitlich

Development of modern concrete fodder silos. H. Hildebrandt. *Zement* (Germany), July, 1930, V. 19, No. 30, p. 709-12.—Concrete fodder silo construction in Germany is described and advantages are discussed. Silos are air-and water-proof. Changes in temperature and internal pressure do not affect structures. Protective coatings make concrete acid resistant. Good heat insulating properties allow complete control of any fermentation process. Silage of excellent properties with high albumen contents can be prepared. Several photographs show different types of silos in use.—A. E. Beitlich

Miscellaneous

Reinforced concrete bins in the German bituminous coal region. Steinheit. *Zement* (Germany), July, 1930, V. 19, No. 27, p. 633-7.—Description of a number of coal bins under construction and completed structures. Reinforced concrete bin near Bitterfeld (Germany) with capacity of 8000 tons coal is 66 m. long, 13 m. wide and 26 m. high. Total of 13,200 cu. meters of ground were removed and 3000 cu. meters of concrete were consumed for this structure. Concrete was placed from distributing tower at rate of about 200 cu. meter per day. Compressive strength after 14 days was between 140 and 160 kg./cm.^{2} Coal distribution tables and conveyor belts are underneath bin. Foundation of coal bin near Meuselwitz consists of continuous concrete slab. Capacity is 1000 tons coal; building is 63 m. long and 7.40 m. wide. Several other structures are described.—A. E. Beitlich

Ground construction. "Der Grundbau." L. Brennecke and Erich Lohmeyer. 1930, 4th edition, Wilhelm Ernst und Sohn, Berlin, R. M. 25.00. Reviewed in *Zement* (Germany), July, 1930, V. 19, No. 28, p. 666.—Book deals with all construction methods for foundation jobs. Special consideration is given to reinforced concrete piles and breakwater construction. Second volume which is still in preparation will complete work on this subject. —A. E. Beitlich

Concrete of any specified proportions produced by Rochester, N. Y., plant. *Pit and Quarry*, May 7, 1930, V. 20, No. 3, p. 76-78.—Describes ready-mix plant of Whitmore, Rauber & Vicinus, near center of city, which delivers to any job in city within 25 min. Firm has been handling aggregates for years. Aggregate portion of plant has capacity of 25 cars per day. Sand and gravel, received in bottom-dump railroad cars, are discharged into track hopper from

which belt feeder loads to inclined belt conveyors. These discharge the material through swivel chute to nine bins or to another belt conveyor which leads to mixing department. Cement is purchased in bulk and unloaded from box-cars by hand-scraper into hopper which feeds chain-bucket elevator. Cement is delivered to two of six bins above mixing department, each of 250-bbl. capacity. Sand and gravel leave bins through quadrant gates, cement through sliding gates. Weighing hopper is equipped with 3-beam scale having dial that registers only last 400 lb. Weighing hopper discharges to another hopper to await dumping into mixer at proper moment. Thus three batches are always in process simultaneously. Water is measured accurately by means of syphon arrangement. Mixer is of 2½-cu. yd. capacity and prepares an average of 350 cu. yd. in 9-hr. day, although it has prepared 400 cu. yd. Mixer is driven by 40 H. P. motor. One man controls mixing department. Concrete is delivered in trucks with bath-tub bodies. Four illustrations.—A. J. HOSKIN

Placing concrete by compressed air. C. H. MUNRO. *Australasian Engineer*, June 7, 1930, V. 30, No. 168, p. 5.—One of earliest pneumatic placers worked on the following principle, and modern methods are but improvements on it: A mass of concrete is placed in a chamber with restricted outlet, and uniform air pressure applied towards the outlet. When, and not until, a further jet of air is blown into the mass near outlet, a small portion, or sub-mass becomes detached and forced into delivery pipe. As each submass is forced into the pipe, the pressure falls and pressure behind mass forces more up to outlet. Process is thus repeated continuously. In later refinements rise in pressure behind the main mass due to cartridge effect of the construction, operates a piston valve in secondary jet line when it reaches a given pressure, adjusted by springs. In practice both valves open almost simultaneously. Various works, mostly tunnels, on which this method of placing concrete has been successfully employed are described. Generally the guns do their own mixing.—JOHN E. ADAMS

Vibrated concrete. E. TREVES. *Le Genie Civil*, (France) June 28, 1930, No. 2498, p. 636.—Vibrated concrete was first tested by Freyssinet in 1917. Making use of compressed air he has since successfully used this method on large scale reinforced concrete construction. Surface vibration was patented in France by M. Berenguier and was commercialized by the society "La Route" since 1927. The vibration of the mass was first introducted by Deniau and has since 1928 been commercially exploited by the Societe des Procedes Techniques de Construction. Advantages of vibration are: perfect homogeniety of concrete, even for dry consistencies; partial elimination of air and water; constant quality concrete permitting a reduction of factor of safety; early removal of forms; good agreement of compressive strengths and their increase from 30 to 200 per cent; constant flexural strength, 16 per cent greater than that of surface vibration only; increased density (1 cu. m. of concrete requires tamping 1200 liters of material; vibration requires 1300 to 1400 liters and pervibration (vibration of the mass) requires 1450 liters. The volume of voids is reduced by one half. The rising of laitance, due to vibration secures a smooth surface. Porosity is reduced and thus danger of infiltration and corrosion by noxious agents. Vibrated concrete is easily adaptable to decorative effects.—M. A. CORBIN

Concrete and reinforced concrete construction. "Fertigkonstruktionen im Beton- und Eisenbetonbau." A. KLEINLOGEL. 1929, Wilhelm Ernst und Sohn, Berlin, 91 pp. R. M. 8.60. Reviewed in *Zeitschrift des oesterreichischen Ingenieur und Architekten Vereins* (Austria), May, 1930, V. 82, No. 21-22, p. 187.—Advantages are described of structural parts of concrete and reinforced concrete which are made in shop ready to put together on job. No forms are necessary and construction can be carried out at much greater

speed. It can be applied to different types of floor construction, large halls, vaults, bridges, breakwaters and railroad structures.—A. E. BEITLICH

Blame divided for Detroit sewer failure. *Eng. News Record*, Aug. 7, 1930, V. 105, No. 6, p. 210-211.—Insufficient soil investigation, inadequate design, inspection and supervision, together with faulty construction, were held by investigating committee to be contributing causes to failure of Detroit sewer. Responsibility was placed jointly on department of public works and contractor. Failure was caused directly by removal of foundation composed of fine water-bearing sand which was carried into the interior of the barrel by groundwater through faulty concrete construction joints and openings developing in barrel after construction. Physical inspection of concrete showed proper proportioning but faulty workmanship in placing, resulting in porous low-strength concrete and thin walls. Thickness of sewer walls was found to vary from 6¾ in. to 26 in. Specifications required minimum thickness of 16 in. Tests of cylinders cored from sewer barrel showed compressive strengths varying from 987 to 6,171 lb. per sq. in. Samples of concrete analyzed in the laboratory showed proportions ranging from 1:2.6:1.8 to 1:3.4:5.3. Although these tests showed evidence of too much sand in the concrete, it might have been due to finely divided quicksand being carried into concrete by infiltering ground water and is not necessarily proof of an oversanded original mix.—D. E. LARSON

Foundations of gas engine plant in Hamborn (Germany). *Zement* (Germany), June, 1930, V. 19, No. 23, p. 541-3.—Foundations for power house with four gas engines is described. Engines are driven with blast furnace gas and furnish compressed air for blast furnaces. Strong vibrations of explosions require special foundation construction. Detailed description of reinforcement is given. Total of 10,500 cu. meters of concrete with 1350 tons of steel were used for foundations; approximately 130 kg. steel were placed in one cu. meter concrete. Water cooling plant and other minor structures consumed 5000 cu. meters concrete.—A. E. BEITLICH

Modern elevator for construction materials. *Zement* (Germany), June, 1930, V. 19, No. 25, p. 595-6.—New type of elevator for rapid transportation of structural materials is described. Highest permissible load is 600 kg. Elevator is easy to install and to move. No scaffolds are necessary.—A. E. BEITLICH

Concrete and reinforced concrete in electro power station construction. BREITUNG. *Zement* (Germany), June, 1930, V. 19, No. 25-26, p. 586-91, 613-6.—Article describes numerous possibilities for application of concrete and reinforced concrete in construction of water and steam power plants for production of electrical energy. Concrete is favorable material for dams and hydraulic structures since good combinations of cements and aggregates guarantee high strength and impermeability. Pressure pipes and intakes can be made of reinforced concrete. Foundations for water and steam turbines can be designed to reduce vibrations to minimum. In generating plants which use steam, concrete is used for construction of coal bins, water tanks, steam condensers and cooling towers. Large field for use of concrete is construction of stacks and poles. Nineteen photographs and drawings are reproduced.—A. E. BEITLICH

Under-water-casting of concrete. W. NAKONZ. *Die Bautechnik* (Germany), Jan., 1930, V. 8, No. 3, p. 35-6.—Methods of casting concrete foundations under water are described. Directions are given for correct working of concrete. Casting must be carried out without any interruption. Funnel must be always filled and movable in all directions. Excavation must be pro-

tected from running water which might cause excessive loss of cement. Difficulties increase with increasing depth of foundation. More than one funnel has to be used when large foundations are placed. Concrete should be earth-moist in order to prevent too rapid flow of mixture. All advantages of different methods and several possibilities for their application are described. —A. E. BEITLICH

Ready-mixed concrete plant for small city. *Concrete*, July, 1930, V. 37, No. 1, p. 27.—Ready-mixed concrete requirements of small city are well covered by small plant of W. A. Gingrich, in South State Street, Ann Arbor, Mich. Sand and gravel are brought, in proper proportions, from commercial pit three miles away. Only material stored at plant is cement. One man employed brings mixed sand and gravel from pit, dumps it into skip of mixer, brings cement from warehouse, charges mixer and sets it into operation, then drives truck around to other side of mixer, dumps concrete and delivers it. Mixing proportions, as a rule, are 1:2:4, but customers are supplied with any proportions desired. A water-control device regulates quantity of mixing water and maintains uniformity from batch to batch. Price for this mixture is $6.50 per cu. yd., delivered.—C. BACHMANN

Chemical technology for contractors. "Chemische Technologie fuer Bauingenieure." DR. FRANZ HEMMELMAYER. 1930, Ferdinand Enke, Stuttgart (Germany). 123 pp., 27 illustrations. R. M. 8.50. Reviewed in *Zement* (Germany), June, 1930, V. 19, No. 23, p. 548.—Book is one volume in Enke's "Collection for Chemistry and Technology." It describes all chemical reactions and materials which are of interest to the contractor. Four parts deal with following subjects: Water and water purification, illumination, explosives and structural materials.—A. E. BEITLICH

New forms and simple apparatus to determine the water permeability of concrete. ERNST RISSEL. *Zement* (Germany), June, 1930, V. 19, No. 23, p. 532-5.—Old methods of determining water permeability of concrete show several disadvantages. Cross-section through which water penetrates cannot be exactly determined. Direction which is studied is mostly vertical to actual direction of water penetration in practice. New forms are described, which allow examination of both directions. Concrete joints are also taken into consideration. Sawing of concrete test cylinders is not necessary and forms can be made with very little costs. Exact dimensions and directions for the preparation of the test pieces are given. Pressure is kept constant by 13 m. high water column. Five test pieces can be connected to this water line. Temperature in room is kept between 15° and 20° C.—A. E. BEITLICH

Reinforced concrete storage silo for malt. F. KOENIG. *Zement* (Germany), July, 1930, V. 19, No. 31, p. 735-6.—Silo which consists of 16 separate compartments has capacity of 4900 cu. meters. Underground was very soft and structure was placed on strongly reinforced Pilz-slab. Twenty-five concrete columns distribute load on foundation. Walls were constructed with sliding forms; they are 17.10 m. high and 15 cm. thick. One cu. meter concrete was made with 310 kg. cement. Cube tests showed 200 kg./cm.^{2} strength after 28 days.—A. E. BEITLICH

Use and abuse of building materials. A. M. GILES. *Builder* (England) June 20 and June 27, 1930, V. 138, Nos. 4559 and 4560, p. 1192 and 1235.—Concrete: It is essential that dry ingredients be well mixed before water is added or voids will not be filled, and sufficient water must be added to cause complete hydration. River water is generally satisfactory if uncontaminated by factory refuse. Sea water may sometimes be used where setting time and appearance are not important. Contaminated water should not be used unless 28-day compression tests give results not less than 80 per cent of clean

water values. It is suggested that correct amount of water may be taken as 28 per cent of weight of cement plus 4 per cent of weight of combined aggregates in mix. The slump test is given in detail, and its frequent application recommended. In experiments with 1:2:4 mix, 17 per cent shrinkage in volume was observed after mixing dry. Final decrease after 28 days, was 27 per cent volume of dry materials. Methods of hand and machine mixing are discussed. For machine mixing, dry materials should be mixed 15-20 secs. Tests show that 5 min. mixing gave 3200 lb. per sq. in. concrete in 28 days, and 1 min. mixing 2900 lb. per sq. in. Many faults are due to insufficient curing. Concrete should be kept damp for two or three weeks. Forms left in place as long as possible retard evaporation. Setting time is determined by flow table. All concretes are more or less permeable, and circumstances affecting this property are many. Clean sand and correct amount of water are main essentials.—JOHN E. ADAMS

ROADS AND PAVEMENTS

Steel forms for road work. *Indian Concrete J.* (India), June 15, 1930, V. 4, No. 6, p. 172.—A new type of steel form is illustrated, which may be used for any thickness of slab between $3\frac{1}{16}$ in. and 9 in. It consists of two steel channels of different sections and a central steel flat. The latter is $1\frac{1}{2}$ in. narrower than the space between the channels and is connected to the support by a countersunk bolt and nut moving in a slot. This arrangement permits vertical movement and leaves spaces through which the reinforcement may pass. No fixing or pegging down of forms is required and there are no loose parts. The method is also applicable to curbing.—JOHN E. ADAMS

Examples of road construction in Vauclose. *Australasian Engineer*, June 7, 1930, V. 30, No. 168, p. 4.)—Road construction in Vauclose is mainly confined to the concrete and bituminous macadam penetration types. The latter is more favored since reasonable serviceable roads are preferred to those with no maintenance costs, but higher first costs. A macadam surface, practically free from waviness has been obtained by handpacking foundations in squares, to a depth of 9 in., the grain of the stone being laid across the road to avoid splitting. For concrete roads longitudinal screeding is recommended because despite the greater number of joints the grain of the surface runs with the traffic.—JOHN E. ADAMS

SHOP MANUFACTURE

Concrete products industry needs more substantial equipment. *Concrete*, August, 1930, V. 37, No. 2, p. 41.—There is little question that the products industry is due for a rather thorough overhauling in matter of equipment, even though several years may elapse before the process is completed. The industry has come a long distance since the day when concrete block machines exhibited at annual cement shows consisted of light-framed contraptions operated by a foot pedal. Now industry is installing heavier and sturdier equipment, fully automatic in its operation. Advantages of this modern equipment are many. It is labor-saving; it places a plant on a large production basis, for a single machine capable of producing six or eight units of standard size in a minute will have a capacity of 3,600 or 4,800 units in 10 hours of actual operation.—C. BACHMANN

Preparing concrete masonry advertising. T. A. DAY. *Concrete*, July, 1930, V. 37, No. 1, p. 35.—Probably best medium for local manufacturer is the newspaper reaching prospective home owners in his community, if he intends to spend his advertising money in residential field. Choose the newspaper that will carry the message to the greatest number of prospects. It is

generally agreed that manufacturer can make no better investment in his merchandising program than to tie in his newspaper advertising with educational copy provided by Architects' Small House Service Bureau. By placing his advertisement in issues in which concrete masonry house is described, he obtains three or four times the advertising space devoted to concrete masonry that he would ordinarily obtain. Success in advertising depends greatly upon ability of advertiser to make reader remember him and his product. Advertisers rely upon repetition of outstanding points to help them obtain new acquaintances and additional users.—C. BACHMANN

Successful piece-work pay system in concrete products plant. R. J. FISHER. *Concrete*, June, 1930, V. 36, No. 6, p. 16.—In general, there are three piece-work payment plans. One consists of paying foreman for all labor. Second system consists of definite apportioning of pay for labor among all men. Third system consists of paying mixer operator, machine operator and off-bearers on piece work basis and hiring day labor for curing room and stock piles. The Economy Concrete Products Co., Milwaukee, Wis., has adopted system under third classification. Prices for each unit of work were determined and set of rules and regulations adopted. These were presented to employees in a letter. Under old system, production per man per 10-hr. day for 8, 10, and 12 in. units averaged about 750, 725 and 500 units respectively. New system averages about 1100, 1050, and 675, respectively. This increase was brought about by using two men to the machine instead of usual three. Production for each machine is but slightly less, from about 2½ per cent for the 8 in. unit to about 10 per cent for the 12 in. unit. The price of 60 to 95 cents a hundred for units from the 4 in. to the 12 in. size is enough incentive to bring production close to the maximum. System is too new to get a detailed report on costs, but taking the average of the 6, 8, 10 and 12 in. units, the cost has been reduced by 0.4 cents per block. It was formerly 2 cents. Under old system it was not uncommon for production to drop 20 to 25 per cent below average daily production, causing wide variation in the cost per unit. Under the new system, labor cost per unit remains the same. Saving is also made in unloading cement. Price of ¾ cents per bag looks low, but has netted men an average of 83 cents an hour. A thousand-bag car is unloaded by nine men in less than an hour.—C. BACHMANN

Well-designed, attractive products plant is credit to industry. *Concrete*, July, 1930, V. 37, No. 1, p. 20.—Cement Products Co., Davenport, Iowa, has a large volume of business in its cast stone work. This means that among the visitors to the plant are people of influence. In their visits they are often investigating merits of material made at this plant as compared with natural stone, or with cast stone made elsewhere. Plant has real business office, located on second floor of building. Principal office space is divided into front office and two private offices. Farther on is the office of the sales manager, while at the far end in the corner of the building, is the office of the president. Building is 2-story structure, built of high-grade concrete units. The structure is 138 ft. by 51 ft. The offices and drafting rooms on second floor occupy a strip about 14 ft. wide. Manufacturing space is rather symmetrical in plan, about 138 ft. long and 38 ft. wide. Each end of the manufacturing space is occupied on ground level by curing kilns, four in each end, and each kiln is equipped with two tracks. Above curing kilns is reinforced concrete floor slab which provides a floor space of about 34 by 40 ft. at each end of the building, these two floor areas being joined by a balcony floor.—C. BACHMANN

Materials

Admixtures

American experiments and experiences with Tricosal. A. Kleinlogel. *Zement* (Germany), Aug., 1930, V. 19, No. 32, p. 758-60.—Properties of Tricosal were carefully examined and it was found that water addition for making of concrete can be lowered about 10 per cent when 1 per cent Tricosal is added. Compressive strength was increased 18 per cent with 1 per cent Tricosal while tensile strength was raised about 43 per cent. Additions of Tricosal improve impermeability of concrete. Briquets were broken and cemented together with Tricosal. After 48 hour storage in moist closet briquets were broken again and all showed new breaks at different places.—A. E. Beitlich

Waterproofing of concrete structures. (See Field Construction—Miscellaneous.)

Lactic acid, mortars and brick floors. (See Properties of Concrete.)

Aggregates

New sand and gravel operation in Philadelphia territory. *Rock Products*, May 10, 1930, V. 33, No. 10, p. 49-53.—Log washers and special types of screens are used to make concrete aggregate from bank material that contains considerable quantities of clay which had hitherto been found difficult to remove. Operation of machines is described in detail with flow sheets and quantities.—Edmund Shaw

Brick and stucco mortars. K. A. Goslich. *Tonind. Ztg.* (Germany), 1930, V. 54, p. 1079-83.—Author thinks that the sand should have sharp corners. After reviewing literature on effect of clay and loam, he points out value of clay in small amounts in filling voids, but states organic matter of humic type must be absent. For stucco the sand must be finer than for brick laying. Also for stucco it has been found (in Germany) that sand containing original moisture makes stronger mortar than if it is allowed to dry out.—F. O. Anderegg

Selection and acceptance of sand and gravel for concrete, especially reinforced concrete. Otto Graf. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 71, p. 1159-60; No. 72, p. 1175-7; No. 74, p. 1203-5.—After the specifications of concrete are determined, careful selection of materials is needed to meet the specifications safely without running too far over. Quality of cement should be uniform. Aggregate should be fairly uniform in grading and to secure this result, sand and gravel should be separated by a ¼-in. screen (7 mm. holes). Gravel should not run much larger than 1¼ in. (30 mm. holes) and should be nearly free from flats. Effect of grading of sand on density, strength resistance to corrosion, etc., of the concrete has been studied and best results are obtained with Fuller curve grading, except that a little more fine material increases resistance to corrosion. Grading recommended is consistent with German and American specifications and is approached by many commercial aggregates.—F. O. Anderegg

Tentative specifications for light weight cast stone (Schwemmsteine) from Bims aggregate. German Standards Committee. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 69, p. 1133.—Bims aggregate is a porous pumice stone which is cast into blocks with lime, standard cement or special cements as binder. The standard shape is 4 x 5 x 10 in., but others are allowed. The maximum weight for this size is 5.34 lb. For compressive strength the flat sides are made parallel with mortar and the air-dry strengths on 10 stones must average 170 lb. per sq. in. when lime is used as the binder, 286

with standard cements and 419 with special cements. The stones must withstand 25 cycles of freezing to 25°F. when saturated with water followed by thawing. These stones have been recognized as fire resistant by the Prussian Ministry for the Peoples Welfare (Voklswohlfahrt). The sp. heat conductivity should range from 2.5 to 3.1 B. T. U. per hr., per sq. ft., per in., per deg. F. difference.—F. O. ANDEREGG

Effect of addition of finer sizes to gravel on strength of concrete. STANTON WALKER. *National Sand Gravel Bul.*, August, 1930, V. 11, No. 8, p. 5-11.—An investigation of strength of concrete, coarse aggregate for which contained varying amounts of finer sizes of gravel, has been carried out in the research laboratory of the National Sand and Gravel Association. This report gives detailed results of tests and some studies of them. Gravel deposits, because of method by which they were formed, often contain an excess of certain sizes which are limited by specifications based on use of arbitrary proportions. Common size to occur in excessive amounts is that generally known to industry as "pea" gravel. Elimination of these sizes often constitutes an economic waste which could be avoided by proper design of the concrete. Ten different gradings of gravel were used, the differences being in amount of No. 8 to No. 4 and No. 4 to ⅜ in. sizes added to a ⅜ to 1½ in. gravel. The tests were divided into two groups. First consisted of studies of 10 gravel gradings in four concrete mixtures as follows: 1-1½-4½, 1-2-4, 1-2½-3½ and 1-3-3. In second group one grading of gravel was tested in mixtures ranging from 1-1-2 to 1-3-6, each containing sand and gravel in proportions of 1 to 2. Compression tests of 6 by 12-in. concrete cylinders and transverse tests of 6 by 6 by 30-in. beams were made. In the concluding remarks the following statements are made: (1) For standard method of molding specimens used in this investigation, it is apparent that 1-1½-4½ mix contained insufficient sand to provide proper workability. (2) Reductions in strength on account of inclusion in ⅜-in. to 1½-in. gravel of relatively large quantities of material between ⅜-in. and No. 8 sieve were comparatively small. Inclusion of 30 per cent of No. 4 to ⅜ in. size decreased strength less than 10 per cent when comparisons were made for same arbitrary proportions. If quantity of sand in mixture is reduced to compensate for increased amount of finer material in the gravel and differences in cement content taken into account, strength is increased in some cases and in other cases reduction is small. (3) In general, reduction in strength on account of the addition of finer sizes was in proportion to additional quantity of mixing water, expressed as a ratio to volume of cement, required to maintain same workability. (4) Both compression and transverse tests in this investigation showed definite relationship between strength and quantity of mixing water, expressed as ratio to volume of cement, and indicated that mixing water was most important factor in controlling strength of concrete. (5) These data indicate that considerable economies may be effected by utilization of finer sizes of gravel.—C. E. PROUDLEY

Aggregate for Boulder Dam. (See FIELD CONSTRUCTION—Dams.)

CEMENT

Determination of sucrose soluble CaO in portland cement. T. F. SEDGWICK. *Rock Products*, May 24, 1930, V. 33, No. 11, p. 81.—Author, an industrial chemist of Honolulu, T. H., states he has found that method of determining sucrose soluble CaO in burnt and hydrated lime appears to give a fair index of the free lime in portland cement. He quotes standard methods for finding sucrose soluble CaO.—EDMUND SHAW

Wage rates and labor conditions in the cement industry in Europe. FRANCIS MILTOUN. *Pit and Quarry*, April 23, 1930, V. 20, No. 2, p. 37-55.—

Economic discussion, by an American who resides in Europe, of the protection given by European countries to their respective cement industries. Wage scales, productions and exports are covered for Sweden, Germany, Belgium, Denmark, France and Italy.—A. J. HOSKIN

The cement industry in Bologna. ANGELO LILI. Reprint from *Il Comune Di Bologna* (Italy), March, 1930, 4 p.—A general description of investigations made in Bologna, which have resulted in conclusion that it is logical location for cement mill. Previously unknown deposits of pure limestone were located and tests show that either natural or artificial cements can be economically produced. National legislation to stimulate construction and thus provide an outlet for production of cement mills in the country is recommended.—C. G. CLAIR AND M. N. CLAIR

A new theory for the fine grinding of cement. O. RAULIN. *Ciment* (France), 1930, V. 35, No. 9, p. 342. Cement may be ground too fine to give best results, the explanation given, being that the air cushion on very tiny particles prevents them from being hydrated. Each cement has a critical grain size which depends upon the burning and which gives the best reaction with water. This critical size should be determined for each cement and then adhered to.—F. O. ANDEREGG

Improvements in cement mill practice. A. B. HELBIG. *Zement* (Germany), Aug. 21, 1930, V. 19, No. 34, p. 796-9.—Author emphasizes importance of installation of air separator in cement grinding mill. Different types of separators are characterized, their advantages described and calculations of their power consumption given. (cf. A. B. Helbig, *Zement* (Germany), Jan., 1930, V. 19, No. 2, p. 25-8 and March, 1930, V. 19, No. 11, p. 237-9.)—A. E. BEITLICH

Practical guide for chemists in the cement industry. "Guide practique du chimiste dans l'industrie du ciment." C. TSOUNTAS. 1929, Editor: *Revue des Materiaux de Construction*, Paris (France), Fr. 20.00. Reviewed in *Zement* (Germany), Aug., 1930, V. 19, No. 32, p. 760.—Book describes analysis of cement, raw materials, fuels, gases, lubricants and water. No consideration is given to physical examination of finished cement. Laboratory test is described which consists of determinations of insoluble residue of ignited raw mix after certain time intervals. It is claimed that results obtained throw light on behavior of clinker in kiln.—A. E. BEITLICH

Burning of lime and cement. J. DEFORGE. *Rev. Materiaux Construction Trav. Publics* (France), 1930, No. 249, p. 212-6; No. 250, p. 262-6; No. 251, p. 298-303.—In the vertical kiln one difficulty is to get the gases properly distributed. One way to improve this is to introduce part of air admitted for combustion through a central chimney. Another kiln is described where producer gas used for fuel is admitted about ⅓ of the way up. Combustion air comes up through the hot lime. The top is closed and the gases are pumped out, being about 40 per cent CO_2 with very little CO, as compared with most shaft kilns where usually relatively large amounts of CO mean waste heat. The CO_2 is purified, cooled and condensed to a liquid; or it may be used in precipitating chalk or for other similar purposes.—F. O. ANDEREGG

Slurry filtration in manufacture of cement. GUSTAV BOEHM AND DESIDER STEINER. *Zement* (Germany), Aug., 1930, V. 19, No. 33, p. 768-75.—Directions for installation and operation of slurry filters in wet process cement plants are discussed. Heat calculations illustrating economy of process are given and tables show relations between water content and specific gravity of slurry. Preliminary tests must be carried out to find suitability of slurry for

filtering process. Slurry which tends to sedimentation is usually well suited for filtration while that which stays in suspension very long is hard to filter. Great uniformity of lime content as well as fineness of slurry is necessary. High temperatures have favorable effect; during winter slurry should be preheated and special care taken to prevent blocking of filters and slurry pipe lines. Continuous stirrers and cleaning every two weeks are suggested. Several different kinds of filters are discussed and their power consumption given. Engineering tests which were made to compare economy of wet process with filter method showed great superiority of the latter.—A. E. BEITLICH

Concrete of great soundness made up of portland cement and arsenious oxide. DONOVAN WERNER AND STIG GIERTZ. *Teknish Tidskrift* (Sweden), April, 1930, No. 5, p. 41-49.—The Royal Engineering Academy of Sweden has for one year carried on tests with a mixture of portland cement and As_2O_3, to find some use for As_2O_3 obtained as a by-product in production of iron in Sweden. This kind of cement is recommended for water resistant concrete, sewer concrete, etc. It was found that setting time could be controlled by heating the mixture. Best result was obtained with a mixture of 70 per cent cement and 30 per cent As_2O_3. For temperatures between 320° and 374° F., setting time was 1 to 3 hours. Higher temperatures delayed the setting. Strength was found greatest for the 30 per cent mixture. Compressive strength of mixture at 7 days was 3890 lb. per sq. in. compared with 2720 lb. for neat cement. After 3 months the corresponding values for the mixtures were found to be 5760 and 7920 lb. per sq. in., respectively. The soundness of the 30 per cent mixture proved to be very good. This mixture decreased the dissolving of CaO from .0507 for 100 per cent cement to .0045. Complete article includes 32 graphical tables.—O. ALBERT.

Is the regulation of the rotary kiln for uniform high efficiency made difficult by great variations of the silica modulus? OTTO FREY. *Zement* (Germany), Aug. 7, 1930, V. 19, No. 32, p. 744-5.—Experiments were carried out with raw materials, which showed great variations in silica content (silica modulus ranging from 2.2 to 7.0). Raw mixture was so proportioned, that modulus was between 3.0 and 3.5. No unfavorable effect during burning process could be noticed. Following observations were made: No ring formations took place when silica modulus was between 3.0 and 3.5; when modulus sank below 3.0, a ring was formed; clinker was black in color and very hard; cement produced was of high quality; sintering point of raw mixture was 1520° to 1530° C. and fuel consumption was 25-26 per cent. Kiln lining was made of Dynamidon bricks.—A. E. BEITLICH.

Breaking down of tricalcium silicate by heat. S. L. MEYERS. *Rock Products*, April 12, 1930, V. 33, No. 8, p. 78-79.—Author found increase of free lime after ignition of cement, the increase being greater with higher temperature and with longer time of heating. This is ascribed to breaking down of tricalcium silicate to dicalcium silicate by heat with consequent liberation of free lime. Experiments on 4 $CaO:Al_2O_3$, Fe_2O_3, 3 $CaO:Al_2O_3$, 2 $CaO:SiO_2$, and 3 $CaO:SiO_2$, all prepared with pure materials, showed that only 3 $CaO:SiO_2$ liberated free lime on ignition. In heating ordinary portland cements, as much as 11.28% of lime has been liberated corresponding to the breaking down of 45.98% of tricalcium silicate to dicalcium silicate. A slightly higher liberation of free lime was obtained with high early strength cement. Clinker or unground cement did not show this reversion with heat. Aged cement was found more susceptible to heat reversion than fresh cement.—EDMUND SHAW

Disturbing effects in portland cement and high alumina cement mixtures. HANS KUHL AND SETSUO IDETA. *Zement* (Germany), Aug. 21,

1930, V. 19, No. 34, p. 792-5.—Portland cement clinker was ground together with different amounts of calcium—alumina melts of different compositions, prepared by fusing mixtures of $CaCO_3$ and Al_2O_3 in oxy-acetylene flame. Composition of melts varied from 3:5 to 4:1 ($CaO:Al_2O_3$). Portland cement clinker and alumina melts were ground separately to fineness of 10 per cent residue on 175 mesh sieve and mixed in proper proportions with an addition of 3 per cent gypsum of same fineness. Following mixtures were prepared: portland cement: alumina melt, 90:10, 75:25, 60:40, 40:60, 25:75 and 10:90. Tensile strength after 1, 3 and 7 days water storage was determined by small-piece testing method proposed by Kuhl. Authors drew following conclusions: melts similar to high alumina cement decrease strength of portland cement after one day when 25 to 40 per cent is present. Alumina melts of composition $2CaO:2.5\ Al_2O_3$ have disturbing effect only when 60 to 75 per cent is mixed with portland cement. When ratio $CaO:Al_2O_3$ becomes greater than 2.5:1, melt has tendency to increase portland cement strength slightly. It is stated that reactions take place between calciumhydroxide, which is formed by hydration of portland cement, and aluminum hydroxide from alumina melt.—A. E. BEITLICH

Experience with slurry filters at the Osborn, Ohio, plant of the Southwestern Portland Cement Co. EARL C. HARSH. *Rock Products*, May 24, 1930, V. 33, No. 11, p. 51-54.—Filters are of the American continuous type. Improvements noted from their installation are: increased kiln capacity, decreased coal consumption, material increase in steam generated by waste heat boilers. Formation of mud rings in kilns has been obviated and clinkers are smaller and burning more uniform. Only one of two 9-disk filters installed has been found necessary. Each 12-ft. disk of 15 sectors has 200 sq. ft. filter area. Palm twill, 15 oz. fabric has given best results. Life was 25 days but by treatment has been increased to 40 days. Cycle uses 40 per cent of time for pickup, 40 per cent drying and 20 per cent discharging. A 28-in. vacuum is maintained by duplex pump and motor. 3 h. p. variable speed motor drives filter through specially designed speed reducer at one revolution in seven minutes. The filter cake goes to a pug mill and is mixed with dust collected by Cottrell precipitation plant. Raw material is ground to 92 per cent passing 200 mesh. Slurry has 35 per cent water which is reduced to 19 per cent by filtering, a removal of 180 lbs. water for each bbl. of cement made.—EDMUND SHAW

Studies on lime—alumina cement I. SHOICHIRO NAGAI. *Kogyo Kwagaku Zasshi* (*J. Soc. Chem. Ind.* (Japan), May, 1930, V. 33, Supplemental binding, No. 5, p. 167-9.—Raw materials which are suitable for manufacture of a lime—alumina cement in Japan were investigated. This kind of cement was proposed by Richard Grün (Tonindustrie Zeitung (Germany), 1924, V. 48, p. 247) and contains approximately 15 per cent silica, 50 per cent lime and 28.2 per cent alumina and ferric oxide. Following raw materials can be used: limestone, puzzolana, loam, colloidal earth and diaspore. Analysis and compositions of these materials are given. Raw mixtures were sintered or melted in electric resistance furnace at temperatures ranging from 1300° C. to 1380° C. Tables show chemical composition of these burns. Hydraulic properties of products obtained were studied by testing on compressive strength of 1:3 cement—sand mortar with small-piece testing method. Cements lose strength in water curing at 7 days with a further considerable decrease at 28 days, but show great increase in strength at 28 days combined curing. It is stated that $5CaO.3Al_2O_3$ or $CaO.Al_2O_3$ are main components in lime—alumina cement from which hydrated product $3CaO.Al_2O_3.3CasO_4.nH_2O$ is dissolved in water which fact decreases its strength. Further studies will cover dusting of heated products, decrease of strength in water curing and increase of strength in air hardening.—A. E. BEITLICH

Long aerial tramway carries limestone to cement mill in the Cascades. FRANCIS CHURCH LINCOLN. *Pit and Quarry*, April 23, 1930, V. 20, No. 2, p. 41-48.—This is a complete description of Superior Portland Cement Company's plant and quarry near Concrete, Wash. Company succeeded Washington Portland Cement Co., the oldest cement company in the state. Limestone occuring in steeply-dipping beds, of various colors and qualities is raw material for wet process. Recrushed stone is belt-conveyed to the loading bin of a double-rope aerial tramway, whence it is transported 6,671 ft. to cement plant at rate of 260 tons per hr. Clay is taken from pit in 5-ton trucks to storage pile at plant. Slurry is pumped to an agitator trough and distributed to tube mills. Six kilns have a combined capacity of 5,200 bbl. per day. Fuel is pulverized coal.—A. J. HOSKIN

Iron oxide vs. alumina as a fluxing agent in the manufacture of portland cement. KATSUZO KOYANAGI. *Rock Products*, May 10, 1930, V. 33, No. 10, p. 82-83.—Author comments on the work of Anton Blank (c. f. *Rock Products*, May, 1928,) with iron oxide and alumina as fluxes in cement. He reviews his own experiments, given in detail, which show that with cement made by Cichibu Cement Co., Tokio, Japan, increasing the Fe_2O_3 content does lessen coal consumption and give a higher tensile strength as Blank claims but it also gives a lower compressive strength. With very high Fe_2O_3 content both tensile and compressive strengths decrease and cement becomes unsound. He notes that Blank experimented with high alumina cement while he experimented with low alumina cement. He concludes that when cement is high in alumina and low in silica, iron oxide can be advantageously used as a fluxing agent, but when cement is low in alumina and high in silica it is better to increase the alumina content a little, leaving the iron oxide content constant. Many tables show results from which conclusions were drawn.—EDMUND SHAW

Analysis of waste gases of rotary cement kilns and their part in kiln control. ALTON J. BLANK. *Rock Products*, May 10, 1930, V. 33, No. 10, p. 58-60.—Comparative tests on the Akron and Orstat apparatus showed they agreed on the CO_2 content of waste kiln gases within 0.1 to 0.2 per cent. Oxygen contents by the Akron device were somewhat erroneous. Carbon monoxide in waste gases was shown by the blackening of silver foil placed under discharge water pipe of Akron device and kiln operators noted this in controlling kiln operation. The reasons for changes in the CO_2 record, such as variation in amount of feed and fuel and the CO_2 content of materials and air and moisture admitted, are listed. Theoretical tables and charts were prepared showing fuel oil consumption for varying percentages of free oxygen in kiln gases and for CO_2 content of kiln gases. These were checked with actual measurements of fuel oil burned and found to be more or less in agreement. Author shows how examination of record may avoid fuel losses.—EDMUND SHAW

Progress in cement research during year 1929. C. R. PLATZMANN. *Zement* (Germany), July 31 and September 4, 1930, V. 19, No. 31 and 36, p. 722-4, 843-7.—Author gives comprehensive bibliography on subjects of recent cement research. Considerable work was done to find favorable relation between chemical constituents, which were expressed by certain moduli, and formulas to obtain best possible cement composition. In close connection with this work were experiments to represent cement constitution and composition by means of graphs and curves. Reactions in kiln and rate of formation of calcium silicates and other clinker minerals were studied by several investigators. Mechanism of setting and hardening process and role of manganese in portland cement clinker were research problems. Synthesis and hydration of calcium aluminates, as well as conditions under which these aluminates form

and exist, were carefully studied. Effect of water soluble admixtures on setting and hardening process of portland cement and high alumina cement was examined. A number of articles deal with relation between fineness of cement and its strength and setting properties. Numerous new methods for chemical analysis and determination of particle size of cement were published. A small-piece testing method, which was developed by Hans Kuhl and modified by S. Nagai, was applied to scientific cement research. Change from normal to quick setting cement on account of heat was studied in various places. Cement specifications were subject of many changes in several countries and new standards were suggested. Relations between fineness and strength, type of storage and strength and between cement strength and concrete strength were investigated. Number of publications deal with investigations of influence of aggressive waters, salt solutions, acids, bases and organic substances on cement, mortar and concrete made of different kinds of cement and cement mixtures. Reactions, which take place when specimens are stored in above solutions, were carefully studied and conclusions on hardening process and durability were drawn. Improvements and new installations in modern cement plants are briefly discussed and several other miscellaneous research subjects mentioned. A total of 129 references are given.—A. E. BEITLICH

Closed circuit dry grinding improves quality of cement. *Rock Products*, April 26, 1930, V. 33, No. 9, p. 56-58.—Superior Portland Cement Co., Superior, Ohio, improved quality of cement and increased plant output 40 per cent by grinding in closed circuit with air separators. Plant is dry process using Bradley mills for preliminary grinding. Material is slag and limestone. After removal of iron by magnetic separator and grinding in Bradley mill material goes to four tube mills in closed circuit with air separators. Five were required before air separation was introduced and a 6-day week is enough to keep kilns supplied for 7-days. Air separators are 14 ft. diameter at top. The feed (tube mill discharge) contains 70 per cent of 200 mesh but much of it is sent back to the tubes. A heavy return has been found to increase grinding capacity and improve quality. Final product of air separators has 87 per cent through 200 mesh which is as good for burning as finer product. Burning is in five kilns. Clinker is coarsely ground in Bradley mill then in four tubes in closed circuit with two 16 ft. air separators. About 35 per cent of what is fed to separators is returned and 70 per cent of this passes 200 mesh. The final product is 95 per cent through 200 mesh. Power required is 35 h. p. for each 14 ft. and 40 h. p. for each 16 ft. air separator. Each tube is driven by a 175 h. p. motor. Output of plant is about 3250 bbl. per day.—EDMUND SHAW

Determination of heats of formation of silicates from their oxides. R. NACKEN. *Zement* (Germany), Aug. 28 and Sept. 4, 1930, V. 19, No. 35-36, p. 818-25, 847-9.—A method is described to determine heat of formation of meta- and ortho-silicates of alkali earth metals from oxides and silica. Heat of solution of silicates in mixtures of hydrochloric and hydrofluoric acid can be measured, and heat of formation can be calculated from obtained data. Reactions are carried out in calorimeter with water thermostat, which keeps outside temperature constant with an accuracy of 1:1000° C. Container is made of platinum and provided with shielded thermometer and stirrer. Specific heat of solvents was determined either by electrical method or by using heat of crystallization of an undercooled solution of salol. Heat of hydration of calcium hydroxide was determined very accurately. Silicates were prepared in electric furnace by heating exactly proportioned mixtures. Following substances were examined and their heat of formation determined: α-$CaSiO_3$ (pseudowollastonite), β-$CaSiO_3$ (wollastonite), δ-Ca_2SiO_4 (calcium ortho silicate), $SrSiO_3$, Sr_2SiO_4, $BaSiO_3$ and Ba_2SiO_4. Difficulties were encountered with barium compounds due to their insolubility, and it was necessary to use pure hydrofluoric

acid instead of a mixture of HCl and HF. Obtained results with barium were not very satisfactory. Attempts were made to study magnesium silicates but without success on account of very slow reaction. Lead silicates were dissolved in mixtures of nitric and hydrofluoric acid and their heat of formation was determined. Formulas for necessary calculations are given, and application of graphic method is described. Reactions which take place in clinker during its formation can be studied under use of above method. (cf. W. A. Roth, *Zement* (Germany), July, 1930, V. 19, No. 27, p. 628-30.)—A. E. BEITLICH

Modern tendencies in the manufacture of cement and inherent dangers. ANGELO LILI. Nomograph, Bologna (Italy), March, 1930, 5 p.—Some of attempts made since 1927 to change requirements of national law in Italy regarding cement strength and density have been toward increase in 28-day compressive strength requirement for "normal" mortar from 3980 lb. per sq. in. to 4960 lb. per sq. in. and a reduction in density limit from 3.00 to 2.90. It is cited that the better cements usually have density of about 3.18 and that only reason for going below 3.00 would be to permit dilution of cement by inert materials. Demand for high strengths at 28 days is difficult to meet by all manufacturers without the use of methods or materials that may be injurious to durability of cement. Best composition of cement with given raw materials is that which has just sufficient lime to combine with the silica and the iron and aluminum oxides. Any other composition will be likely in time for form unstable compounds. The cements of proper composition (hydraulic modulus not exceeding 2) show large increases from 7 to 365 days, and even with the tensile strengths, about 1/10 of the compressive strengths. High hydraulic modulus gives high early strengths, but relatively small increases between 7 and 28 days, and sometimes retrogression thereafter. Instability of volume and low tensile strength also occur with a high modulus. Author urges the State to make investigation covering all types of cements produced, and from that data to set up only important requirements. He states trend toward high strengths is absurd because the result is use of more steel, formation of more cracks, more chance of corrosion of steel, and much question as to durability of concrete. It is suggested that cements meet a requirement for "normal" mortar of 256 lb. per sq. in. in tension, and 2560 lb. per sq. in. in compression at 7 days, with appreciable increase at 28 days and beyond. Also that every bag of cement sold bear a diagram showing the normal strength—age curve for the cement, and name of manufacturer, addition of inert material to be prohibited. Specification based on the 7 day test is also proposed as follows:

$$N = \frac{f_7 \text{ (compressive strength of normal mortar at 7 days)}}{7},$$

28 day strength $= \frac{N}{a} \times 28$, 365 day strength $= \frac{N}{b} \times 365$, with suggestion that $a = 3$ and $b = 20$. Strength in tension at 7 and 28 days should be about 1/10 of the compressive strength. The advantages claimed for this specification are that this allows manufacturers to obtain best combination of raw materials and cements of highest value, for their conditions and provides a minimum strength requirement that will meet average demand, but which does not restrict production of higher strength cement.—C. G. CLAIR AND M. N. CLAIR

Blast furnace slag cements. A. O. PURDON. *Rev. materiaux construction trav. publics* (France), June, 1930, No. 249, p. 205.—American readers will find

definitions of: (a) "iron portland cement" (ciment portland de fer) as a mixture of a minimum of 70 per cent portland cement clinker with granulated blast furnace slag; (b) of "blast furnace slag cement" (ciment de haut fourneau) or "slag portland cement" (ciment portland de laitier) as mixtures as above containing lesser percentages of portland cement clinker. These are not to be confused with "slag cement" proper (ciment de laitier), a mixture of slaked lime and slag without addition of clinker. The article is a summary of test evidence showing that strength of blast furnace slag cements is equivalent to that of portland cement after a sufficiently long time interval. Clinkers of different origin were mixed in laboratory with various slags. The "ideal" proportions were computed making all of free lime in clinker become saturated by acid components (silica and alumina) of the slag. Uniform fineness was insured by grinding the two constituents separately before mixing. Tests show that "ideal" proportions are actually most advantageous. Admixtures of clinker exceeding this optimum (34.7 per cent) result in no further increase in strength, but act to reduce it. Commercial blast furnace slag cement was compared with standard portland and rapid-hardening portland cements, mostly of Belgian origin. The tests showed that, while during the first days slag cement lags considerably behind portland, at 3 mo. their strength values are very close and at 1 year almost identical. Tests at ages of 5 and 10 years are scheduled. Comparison is made with strength tests at 2 years of iron portland cement made in Germany by Tetmajer and Michaelis. The "iron portland" cements were recognized as equivalent in strength to standard portland in 1909 after a bitter struggle of 8 years. Objectors to "blast furnace slag" cements have emphasized the presence of calcium sulfate in slag with consequent danger of liberation of sulfuric acid. This acid, however, becomes immediately neutralized by lime continually formed during the setting and hardening of cement. Another argument relative to expansion of blast furnace slag cements is not confirmed by actual experience, these cements showing in a high degree the desired constancy of volume. According to Fritsch, the blast furnace slag cement shows remarkable resistance to saline waters, in which property it excels the standard portland cement. Finally, its low cost, due to the almost negligible cost of slag entering into mixture to extent of 70 per cent, makes it a most desirable product.—M. A. CORBIN

MISCELLANEOUS

A high-sensitivity absolute-humidity recorder. CRANDALL J. ROSECRANS. *Ind. Eng. Chem.*, Analytical Edition, V. 2, No. 2, p. 129-134.—An apparatus has been developed for measuring and recording the amount of water vapor in the air, which is suitable for recording humidities from zero up to saturation within a temperature range from 100° to about 200° C. This apparatus is based on measurement of the thermal conductivity of water vapor and air mixtures and is continuous reading.—ROY N. YOUNG

Tricalciumsilicate. RUDOLF BRILL. *Zement* (Germany), Aug., 1930, V. 19, No. 34, p. 796.—Tricalciumsilicate was prepared by fusion of mixture of CaO and SiO_2 in right proportions and keeping product at temperature of 1500° C. for 3¼ hours and following quenching. Comparison of its X-ray diagram was made with X-ray diagram of dicalciumsilicate and complete similarity was found. Author claims that tricalciumsilicate does not exist, and obtained product is only mixture of dicalciumsilicate and free lime.—A. E. BEITLICH

A stucco that did not harden. OTTO FRIZ. *Tonind Ztg.* (Germany), 1930, V. 54, No. 65, p. 1070-1.—A row of houses built of lightweight concrete block of pumice stone (Schwemmsteine) was covered with stucco, the first coat being a white lime mortar containing a little portland cement and applied to the well wetted walls. The second coat was a gray or dolomitic lime mortar.

Stuccoing was done in the fall and damp weather of late fall and early winter prevented the well soaked walls from drying so that the lime did not harden until a warm spell of weather in February permitted moisture to evaporate.—F. O. ANDEREGG

Contribution to the knowledge of ceramic properties of lime—alumina—silicates and refractory and high refractory materials. E. BERL AND FRITZ LOEBLEIN. *Forschungsarbeiten auf dem Gebiete des Ingenieurwesens* (Germany), 1930, No. 325, 28 pp.—Investigations were carried out to study softening and melting points of pure chemical melts and refractory bricks, composition of which falls in the system CaO—SiO_2—Al_2O_3. Special consideration was given to heat conductivity. Diagram is given showing relation between softening point and melting point and chemical composition. Graphs show compounds with like properties in three-component system. Mechanical strength depends very much on silica contents. Method is derived which allows determination of true heat number, which factor expresses heat conductivity.—A. E. BEITLICH

Types of minerals in artificial melts of $2CaO.SiO_2$, $3CaO.SiO_2$ and $8CaO.2SiO_2.Al_2O_3$. KATSUZO KOYANAGI. *Kogyo Kwagaku Zasshi* (*J. Soc. of Chem. Ind.* (Japan), May, 1930, V. 33, Supplemental binding, No. 5, p. 161.—Author prepared following melts: $2CaO.SiO_2$, $3CaO.SiO_2$ and $8CaO.2SiO_2.Al_2O_3$ from purest raw materials and studied their thin sections under microscope with polarized light. In all specimens an abundant amount of crystal needles with strong double refraction was found, especially in the $2CaO.SiO_2$ compound. Needles are believed to be dicalcium silicate. In $3CaO.SiO_2$ crystals were found with weak double refraction, corresponding with "alit." Free lime crystals were found under microscope in melts which showed great amount of free lime by glycerol method.—A. E. BEITLICH

Corrosion of Lead in Buildings. *Engineering* (England), April 11, 1930, p. 494.—Lead is usually resistant to corrosion since the surface exposed to moisture, oxygen and carbon dioxide is converted into a protective film of basic lead carbonate (mixture of lead carbonate and hydrate) but if CO_2 is lacking lead oxide is dissolved or if CO_2 is present in excess the oxide film is changed to soluble bicarbonate, and in either case corrosion results. Instances of failure have occurred caused by contact of lead with cement. Corrosive action of cements and mortars in presence of water, oxygen and carbon dioxide appears to depend upon their content of free lime, which absorbs carbon dioxide preventing formation of protective film of basic carbonate, and partly as a solvent exposing fresh surfaces for attack. Aluminous cements, containing no free lime show no progressive attack on lead. Old cement and mortar, the lime of which has been completely carbonated is also inert. Tin coatings offer greater resistance to attack than leads. To protect lead from corrosive action of cement of mortar, good practice is to provide a protective coating of bitumen.—G. M. WILLIAMS

Studies on fundamental synthesis of calcium aluminates and their hydration VI. SHOICHIRO NAGI AND RYUICHI NAITO. *Kogyo Kwagaku Zasshi* (J. Soc. *Chem. Ind.* (Japan), Jan., 1930, V. 33, Supplemental binding No. 1, p. 37-43.—Test data are given, which show rate of combination when mixture of $CaCO_3$ and Al_2O_3 in ratio of 3 CaO to 1 Al_2O_3 is heated. Comparisons are made with data obtained by preparation of $5CaO.3Al_2O_3$, $CaO.Al_2O_3$ and $3CaO.5Al_2O_3$, which were reported in previous article (*Kogyo Kwagaku Zasshi* (Japan), 1929, V. 32, p. 965). When a mixture with ratio 5CaO to $3Al_2O_3$ is heated, it tends to form $3CaO.Al_2O_3$ with increasing temperatures.—A. E. BEITLICH

The bauxite deposits of the Ariege. V. CHARRIN. *Genie civil* (France), Sept. 20, 1930, No. 12, p. 281.—Ariège bauxites are least accessible deposits,

being located in foothills of the Pyrenees. The stratum runs east and west and seems to be result of tremendous upheaval. The average width of workable stratum is about 3.4 miles. Its thickness varies from a few inches to from 20 to 25 ft. White, red and all intermediate shades are represented in this deposit. The analysis of red low-silica bauxite is: alumina, 62 to 65 per cent; silica, 6 to 7 per cent; iron oxide, 12 to 15 per cent. Low-alumina refractory bauxite has following analysis: alumina, 40 to 44 per cent; silica, 36 to 40 per cent; iron oxide, 1 to 3 per cent. The average run of bauxite has following quality: alumina, 50 to 55 per cent; silica, 15 to 18 per cent; iron oxide, 10 to 15 per cent.—M. A. CORBIN

Studies on fundamental synthesis of calcium aluminates and their hydration IV. SHOICHIRO NAGAI AND RYUICHI NAITO. *Kogyo Kwagaku Zasshi* (*J. Soc. Chem. Ind.* (Japan), May, 1930, V. 33, Supplemental binding, No. 5, p. 164-6.—Authors report further studies on three eutectic mixtures: (1) 47 per cent CaO:53 per cent Al_2O_3 which is eutectic between $5CaO.3Al_2O_3$ and $CaO.Al_2O_3$; (2) 2CaO:1 Al_2O_3 which is nearly equal to eutectic mixture of 50 per cent CaO:50 per cent Al_2O_3 and (3) 33.5 per cent CaO:66.5 per cent Al_2O_3 which is eutectic between $CaO.Al_2O_3$ and $3CaO.5Al_2O_3$. Temperatures are given at which combination of these compounds is completed. Compound $2CaO.Al_2O_3$, which was reported as pure aluminate is now believed to be mixture of $3CaO.Al_2O_3$ and $5CaO.3Al_2O_3$. Compressive strength was studied of obtained products by small-piece testing method proposed by authors. Further investigations of compounds: "alit," "celit" and "gehlenit" are under way.—A. E. BEITLICH

Action of salts, acids and organic substances on cement and concrete. RICHARD GRUN. *Zeitschr. angew. Chemie* (Germany), June 14, 1930, V. 43, No. 24, p. 496-500.—Investigations were carried out to study influence of solutions of different concentrations of acid salts, free acids and organic substances on setting time, compressive and tensile strengths of portland cement and blast furnace slag cement. Concentrated solutions of calcium chloride accelerate setting process, but with increasing dilution, setting time becomes longer for both cements. Ferric chloride, aluminum chloride and mixture of calcium chloride and aluminum chloride have similar effects. Barium chloride has little influence. Initial tensile strength is usually lowered, but will be normal at 28 days. Compressive strength is only lowered by concentrated solutions, while diluted solutions improve strength, especially after 28 days. Hydrochloric acid leads to shortest setting times with great evolution of heat. With concentrations of 1.1 and 1.8 per cent, tensile strength is lowered in most cases but compressive strength shows great increase. Organic substances slow up setting process and destroy nearly all strength properties. Hardened concrete test pieces of 1:3 cement—sand mixtures were stored in phosphoric acid and oxalic acid up to one year. Concentrations of phosphoric acids were 5, 10 and 15 per cent, oxalic acids 1 and 5 per cent. Both cements passed tests fairly well. No visible effect could be observed after six months storage in 5 per cent phosphoric acid. Strength decreases after this period. Stronger acids have destroying influence after short time. Oxalic acid shows in general no influence, 5 per cent concentration causing small decreases in strength. Normal strength was noted after one year. Several references are given.—A. E. BEITLICH

The Italian cement, lime and gypsum industries. (See MATERIALS—Cement.)

New dry paint for the concrete brick industry. (See SHOP MANUFACTURE.)

PROPERTIES OF CONCRETE

Remixing cement mortar—building research station. *Builder*

(England), Sept. 12, 1930, V. 139, No. 4571, p. 440.—Results of tests on retempering are given, and it is stated that although with portland cement it may be possible to regauge the mortar after a period up to four hours, with rapid hardening cement a definite loss of strength is indicated. Further if a wet mix were allowed to stand and evaporation of excess moisture resulted, a slight increase in strength for this reason alone, might be registered. The practice in general is not recommended.—JOHN E. ADAMS

New fundamental questions concerning concrete composition. Abram's aggregate modulus and Spindel's graphic concrete synthesis. OTTOKAR STERN. *Zeitschrift des oesterreichischen Ingenieur und Architekten Vereins* (Austria), Aug., 1930, V. 82, No. 31-32 and 33-34, p. 255-7, 269-72.—Discussion of theory of four-component system and its application for calculation of concrete mixtures is given. Relation is shown between w/c-ratio and amount of dry solid substances. Formulas are given for calculation of voids and solids. In order to obtain best concrete consistency certain mixing rules are suggested which connect Abram's modulus, w/c-ratio and compressive strength. Limits for possible cement mixtures are calculated and directions are given for making of charts for above graphic calculations.—A. E. BEITLICH

The failures of mortars and concrete. "Les defauts des mortiers et des betons." J. MALETTE (France), Francs 63.50. Reviewed in *Der Bauingenieur* (Germany), May 9, 1930, V. 11, No. 19, p. 342.—First part discusses limes and cements, their constitution, chemical composition, behavior in sea water and specifications. Second part describes aggregates, mortar and concrete and illustrates all facts, which influence their normal behavior. Effect of aggressive waters and chemical substances on concrete is characterized. Numerous tests and experiments made by author conclude book.—A. E. BEITLICH

Chemical composition of outer layers of cement mortars and concrete II. SHOICHIRO NAGAI AND K. JOSHIWAZA. *Kogyo Kwagaku Zasshi* (J. *Soc. Chem. Ind.* (Japan), Jan., 1930, V. 33, Supplemental binding, No. 1, p. 43-8.—Experiments were made with mixed 1:2 mortars and w/c ratios ranging from 50 to 70 per cent. It was found, that loss on ignition and amount of calcium carbonate in outer layer increase with increasing w/c ratio. Sulphuric acid content increases simultaneously. Similar results were obtained with neat cements.—A. E. BEITLICH

Bond strength and resistance of concrete to impact and wear compared to its strength in compression, flexure and tension. R. FERET. 1930, Published by *Rev. materiaux construction trav. publics*, Paris (France), 1 V., 72 p.—The author distinguishes two fundamental classes of strengths: compression and shear, proportional one to the other, and tension and flexure, equally proportional one to the other, but showing no fixed relation with respect to the former. Personal experiments and detailed study of data from other sources show that in a series of mortars or concretes made with the same cement and differing by one variable factor only, tensile (or flexural) strength increases less rapidly than compressive strength and varies approximately as the 2/3 power of the latter. In mixes of varying composition, the relation of the former to the latter strength is approximately proportional to that of quantities of water and cement. This discrepancy between the two classes of strengths depends to a large extent on the fact that composition near the surface of test specimen is rarely identical with that of the core, due partly to unequal distribution of materials against the walls of the mold, and partly to unequal hardening of the mass, the curing medium having a more direct effect on some parts of the specimen. Aside from this, strengths are variably in-

fluenced by latent stresses, varying according to the distance from the exposed surface, and produced by changes in volume as a result of chemical, thermic and hygroscopic action. It thus appears that tests of concrete in tension and flexure do not show adequately the stresses of similar nature which concrete will withstand on the job, while compression strength values are proportional to actual strengths. Resistance to shock and wear, as well as bond strength differ from the fundamental classes of strengths, but appear in certain series of concrete tests to be proportional to one or the other group. Resistance to wear by abrasion depends almost entirely on the hardness of the rock materials used in the concrete.—M. A. CORBIN

Lactic acid, mortars and brick floors. E. SUENSON. *Der Bautenschutz* (Germany), 1930, V. 1, No. 1, 2, 4 and 6, p. 3-6, 30-3, 59-63, 80-5.—Comprehensive investigation was undertaken to study influence of lactic acid on cement mortars. Acid was used in three different concentrations: 1/10, 2/10 and 3/10 normal with pH:2.4, 2.3 and 2.2. Following kinds of cements were tested: (1) portland cement, (2) portland cement with admixture of Ceresit, (3) portland cement with Sika 1, (4) portland cement with Sika 4a, (5) Danish Velo cement, (6) French Alzement (high alumina cement) and (7) American Medusa White cement. Test pieces made for study of volume changes in mixtures 1:2 and 1:4 were immersed in pure water, three lactic acid solutions of above concentrations, milk and butter milk. No considerable changes in volume were observed. Solutions showed different grades of aggressive action on cements. Effect of hot and cold water on volume of test pieces was investigated. Strength tests were carried out with 1:4 mortars with small slabs and cubes which were stored in lactic acid solutions. Compressive and flexural strength properties were studied. Lactic acid lowers compressive strength much more than flexural strength. None of the special cements or mixtures showed much better behavior than ordinary portland cement. Resistance to acid and relation between compressive and flexural strength increases very much with cement contents and coarseness of sand.—A. E. BEITLICH

ENGINEERING DESIGN

BRIDGES

Handbook for reinforced concrete. III. "Handbuch fur Eisenbeton." W. GEHLER. 1930, Wilhelm Ernst und Sohn, Berlin (Germany), V. 4, new edition, R. M. 6.80. Reviewed in *Der Bauingenieur* (Germany), May 23, 1930, V. 11, No. 21, p. 373.—Subjects of book are calculations and construction methods of reinforced concrete bridges, construction of roadways, joints, abutments, piers and hinges. Several outstanding bridge structures are discussed.—A. E. BEITLICH

Queen Margaret bridge, Glasgow. *Concrete Constr. Eng.* (England),

Sept., 1930, V. 25, No. 9, p. 510.—The bridge is a simple parabolic arch, having a skew span of 137 ft. between abutments. Angle of skew is 26 degrees. A subway is arranged over each abutment for traffic along the river. Some difficulty was experienced in the design of one of the abutments, owing to the presence of a 5 ft. brick sewer, which followed the line of the abutment beam. Difficulty was overcome by providing reinforced concrete beams over the sewer so horizontal component of thrust was taken over top of sewer. Reinforced concrete was used exclusively for the structural work and parapets of bridge were of red granite.—J. MARIN

Stresses under the Freyssinet method of concrete-arch construction. J. T. THOMPSON. *Eng. News Record*, Aug. 21, 1930, V. 105, No. 8, p. 291.—The principal advantages and economics claimed for Freyssinet method of concrete-arch construction may be briefly summarized as follows: (1) Elastic rib shortening and shrinkage stresses may be practically eliminated, with reductions in rib sections. (2) By postponing the keying until temperature of air has reached a desirable mean value, temperature stresses may be considerably reduced. (3) Secondary stresses due to lateral deflection of abutments may be practically eliminated. (4) Continuity may be developed at ends of centers in long spans, thus reducing deflections. Centers are struck by exerting jack pressures that widen the opening at the crown a sufficient amount to lift the rib clear of the centering. Author presents data relative to stresses in typical Freyssinet concrete-arch bridges in France where method has been used extensively and points out that highest stresses may be reduced as much as 35 per cent.—D. E. LARSON

BUILDINGS

A large reinforced concrete aeroplane hangar. C. E. HOLLOWAY. *Struct. Eng.* (England), Sept., 1930, V. 8., No. 9, p. 317-328.—A design in reinforced concrete, submitted in open competition with steel, was chosen for an aeroplane hangar having a clear floor area of 80 by 100 ft. and built at Heston Air Park, Middlesex, England. The design is featured by r. c. tied arches of 100 ft. clear span and 20 ft. rise, spaced 16 ft. on centers, and mounted on lead sheets. Main columns are provided with side wind struts which slope away from the tops of columns at 45 degrees. Wall panels were cast into preformed grooves in sides of wall members, thereby confining cracks to the grooves. Office and shop space is provided on the sides of the structure beneath wind struts and additional office space was made overhead between walls and adjacent arches, floors for the suspended offices framing into the arch ties. Analysis and details are given for arch ribs, hangers, ties, columns and struts.—V. P. JENSEN

Concrete airship hangar of bold design at Sevilla, Spain. A. A. PETERS. *Eng. News Record*, Aug. 28, 1930, V. 105, No. 9, p. 324.—Huge arched-roof hangar of reinforced concrete in unusual and bold design is being built for airships of Zeppelin type at Sevilla, Spain. Designed to hold two large dirigibles, it is 950 ft. long, 400 ft. wide and 200 ft. high. Plans were based on those developed for small war-time steel structure planned for Italy. It was proposed to utilize a portion of old steel shipped to that country prior to signing of armistice. This plan proved to be futile and cost study indicated that arch design in reinforced concrete would be cheaper than modern structural steel building. Structural steel centering is being used for arches and quick-setting cement is being imported from England to cut down time limit on removal of supporting forms and speed up cycle of operations for each setup. Cement gun is being used to place concrete in wall of bays between arch ribs. These walls are only 4 in. thick and contain double lines of reinforcing bars.—D. E. LARSON

DAMS

Circular concrete arch dam designed by simple method. R. P. V. MARQUARDSEN. *Concrete*, Oct., 1930, V. 37, No. 4, p. 27-29. Author outlines a method of calculating fibre stress in concrete of a fixed-end circular dam with a constant cross section in any horizontal plane. An elevation of the arch is drawn, a base line is established to permit proper application of the stress formula to the extrados and intrados sides of the various sections of the dam. The formula for fibre stress at any section involves water pressure, radius of curvature to both the center of the dam and the upstream face, thickness of dam or arch, coefficient of expansion or contraction, temperature changes, amount of settlement, modulus of elasticity of concrete, various angles including the central angle of the arch, and three sets of quantities which are functions of the central angle and which are given in three charts. Calculation of fibre stress for crown and end sections are very simple. Shearing stresses may be found by a simple formula submitted. Derivations of formulas given are to be published in November issue of Concrete.—N. H. ROY

MISCELLANEOUS

Nomogram for calculating slabs and beams, for calculating moments for different conditions of the supports. JORGE QUIJANO. Ingenieria (Mexico), March, 1930, p. 123 and 133.—Simple alignment or nomographic charts, of a series of such charts for use in reinforced concrete design, one solving the relation between M and A_s and d for given values of f_s, f_c and N. Left hand scale or line l middle scales A_s and d, and right scale W. All in metric units. The other chart solves the relation $M = CWl^2$. Left hand scale or line l, middle scale M, and right scale W.—C. G. CLAIR AND M. N. CLAIR

Slurry mixing tanks. *Concrete Constr. Eng.* (England), Sept., 1930, V. 25, No. 9, p. 513.—Reinforced concrete has been used exclusively at the Johnson's Works of the British Portland Cement Manufacturers, Ltd., for the construction of slurry mixing tanks. Details of tanks are given. Range in size is from 48 to 66 ft. internal diameter. They are 11 ft. 6 in. deep and the walls are 6 in. from top to bottom. Details of the design and of construction are given.—J. MARIN

Construction of reinforced concrete superstructures. "Practisches Konstruieren von Eisenbetonhochbauten." RUDOLF BAYERL AND ADOLF BRZESKY. 1930, Julius Springer, Vienna, 144 p., 67 illustrations, R. M. 7.00. Reviewed in *Die Bautechnik* (Germany), June 13, 1930, V. 8, No. 26, p. 418.—Design and calculation of superstructures are illustrated. Examples are included for different types of ceilings, columns, slabs, girders and frames. Influence of heat and shrinkage on structure is shown.—A. E. BEITLICH

Reinforced concrete coal bin. *Zement* (Germany), April 17, 1930, V. 19, No. 16, p. 386.—Structure has cross section of 46½ ft. square and capacity of 1200 tons. Total height is 120 ft. Bin rests on four closed frames, which are supported by eight vertical reinforced concrete columns. Foundation consists of continuous slab. Pumping station is located in basement of structure and pumps water to three water tanks on top of bin.—A. E. BEITLICH

Reinforced concrete design simplified. JAMES R. GRIFFITH. *Concrete* Sept., 1930, V. 37, No. 3, p. 35-37.—Chart A, given in Concrete, March, 1928, has been modified to allow higher strength concrete and higher working stresses allowed by the A. C. I. Code. Balanced tensile reinforcing for concrete beams may be had directly from the chart. The factors involved are breadth and

depth of beam, bending moment, steel area, and allowable stress in the concrete.—N. H. ROY

Statics of structures (in three volumes). "Die Statik der Bauwerke (in drei Baenden)." RUDOLF KIRCHHOFF. 1930, Wilhelm Ernst und Sohn, Berlin (Germany), 2nd V., 2nd edition, 368 p., 261 illustrations, R. M. 27.00. Reviewed in *Die Bautechnik* (Germany), June 13, 1930, V. 8, No. 26, p. 415.—Book deals with static calculations of form variations of structures. Construction of bridges (except suspension bridges) and of other kinds of superstructures is discussed. Beams, girders, columns and slabs are analyzed and their calculation illustrated. Ceiling and wall structures conclude book and third and last volume will appear very soon.—A. E. BEITLICH

Reinforced concrete shell roofs. H. SAVAGE. *Concrete Constr. Eng.* (England), Sept., 1930, V. 25, No. 9, p. 490-1.—Theory developed for the design of two kinds of shell roofs: shells curved in one direction and in two directions. Theory covers cases of unsymmetrical loading, any degree of fixation at the boundaries of the shell and any form of the shell itself. Approximate solutions are presented to simplify design. Experiments were made on large scale models to verify degree of accuracy attained in calculations by approximate methods. Main feature in design is reduction of bending moments in the shell. A graphical method of analysis is given for cases where the curve of the shell cannot be expressed mathematically, or shell varies in thickness, or load is complicated. Examples of various types of shell roofs are given. References for further information on shell roofs are cited.—J. MARIN

Reinforced concrete design simplified. JAMES R. GRIFFITH. *Concrete*, Oct., 1930, p. 39-40.—Professor Griffith presents Charts F_1 and F_2 for the determination of stirrup spacing when allowable stirrup stresses of 14,000 and 12,000 lbs. per sq. in. are desired. The formula for spacing conforms to the Joint Committee and A. C. I. Code. Only the excess of shear above 40 lb. per sq. in. is used in the charts. The charts involve breadth of beam, excess unit shear, stirrup spacing, and size of bars.—N. H. ROY

Economic designs of reinforced concrete walls and ceilings using "disk" effect. H. CRAEMER. *Zement* (Germany), July 24, 1930, V. 19, No. 30, p. 703-8.—A theory is derived which explains "disk" effect or mutual influence of neighboring structural parts on account of monolithic structure of concrete. Neutralization of certain stresses takes place. Economic importance is very evident in structures like silos and storage bins. Walls take up part of stresses and eliminate necessity of supporting beams. Diagrams show stresses occurring in such walls. A number of examples of practice indicate that more than 360 cu. yd. of concrete were wasted for construction of ten useless transverse beams in coal bin structure of average size. Other examples show "disk" effect in ceilings where horizontal stresses are taken up.—A. E. BEITLICH

New York subway construction. *Eng. News Record*, Aug. 7, 1930, V. 105, No. 6, p. 200-205.—New York City's third subway system, one of the great construction undertakings of the world is now more than 60 per cent completed. Construction and equipment cost of 55 miles of line will be $650,000,000. Virtually, design of each type of present subway structure is same as employed for corresponding type in older subways. The structure in open cut consists of transverse steel bents every 5 ft. with columns in wall lines and between tracks. Columns stand on concrete footings and concrete jack arches fill between wall columns and roof beams. Subway tunnel structure in rock consists of semicircular concrete arch over each track with row of columns between tracks carrying longitudinal girder against which opposed arches thrust. Soft ground and subaqueous tunnels are lined with cast iron segments with interlining of concrete to give smooth surface. Only exception to this

structure is ¼-mile shield tunnel lined with precast concrete blocks.—D. E. LARSON

Stress transmission in frictional-cohesive materials. R. W. H. HAWKEN. *J. Inst. Eng. Australia* (Australia), July, 1930, V. 2, No. 7, p. 247.—Author propounds and solves a general theorem of stress transmission in frictional—cohesive materials on the verge of movement, and correlates with it results of Rankine, Navier, Bell and Resal. In "general equation," giving the relation between principal stresses, cohesion and friction, it is usually assumed that one principal stress is represented in direction and amount by intensity of applied normal load, given by gravity in earthwork or by the testing machine in compression tests. For cohesive materials, author considers this untrue when movement is just about to take place. The potential tangential resistance to movement, due to cohesion is considered to be a supplementary shear stress introduced as a maximum on one plane in material with infinitesimal cohesion —that is to say non-cohesive material. This one plane will be critical plane in frictional cohesive material. Direction of principal stresses for assumed criteria of incipient movements is deduced by applying principle of component additions and in the ellipse deduced, the general equation is fulfilled. On critical plane, cohesion which is maximum potential resistance to shear, independent of normal pressures, and potential frictional resistance proportionate to normal stress, taken together, equilibrate the shear concomitant with the true principal stresses.—JOHN E. ADAMS

Statics of restrained and continuous beams. FRITZ EMPERGER. *Beton u. Eisen* (Germany), June 20, 1930, V. 29, No. 12, p. 216.—The moment curve can be exactly determined only for simply supported beams. Where restraint exists the moment variation may be studied by considering possible limiting conditions of restraint. Usual assumption of point supports, satisfactory in bridge work does not seem reliable for buildings where the columns act with the beams. Until recently all steel beams were designed for a moment of $\frac{wl^2}{8}$ throughout their entire length regardless of end restraint. The Austrian Reinf. Conc. Committee in 1908 (Heft 5, 1916) conducted some tests on restrained steel beams of 13 ft. spans. At that time restrained concrete beams were designed for a center moment of $\frac{wl^2}{10}$ while $\frac{wl^2}{8}$ was required for steel beams. The tests showed a completely fixed condition for steel beams with ends built in brickwork with portland cement mortar, and in concrete. Only partial fixity was found for brickwork with lime mortar. The Committee then recommended for steel beams so restrained, a resisting moment at center and at supports of $\frac{wl^2}{16}$. Later tests bear out 1908 investigation (c. f. Maier-Leibnitz, *Bautech.* 1929, Heft 20). Building departments of Leipzig and Hamburg have now approved this recommendation. Safety against failure should be governing factor in beam design. The sum of the center and support moments rather than moment at any one point is to be considered. Attainment of elastic limit at any point leads to a readjustment of moment curve, causing higher moments at other portions of beam. In concrete flexibility of design possible in reinforcement and haunching permits original moment distribution between center and supports to exist until failure. Tests deal with this problem. In tests by Austrian Reinf. Conc. Committee (Heft 4, 1913) a fully restrained concrete beam was reinforced for $\frac{wl^2}{24}$ at supports and $\frac{wl^2}{12}$ at center. At failure, the moments had adjusted themselves to fit this steel distribution. It is hoped to continue at some future date tests of duplicates of single span restrained beams already studied, when these beams are parts of rigid frames.—A. A. BRIELMAIER

A new construction principle. (See FIELD CONSTRUCTION—Miscellaneous.)

ROADS AND PAVEMENTS

Concrete roads—joints. *J. Inst. of Municipal County Engineers* (England), Sept. 2, 1930, V. 57, No. 5, p. 22.—The Ministry of Transport and the County Surveyor of Surrey are collaborating for the purpose of investigating the properties of different types of joints in concrete roads, and the most important relating to the experimental section of road are given.—JOHN E. ADAMS

Joints in concrete roads. *Concrete Constr. Eng.* (England), Sept., 1930, V. 25, No. 9, p. 523.—Study of failure of roads recently built in England shows the striking feature that in practically every case the defect is at a joint. A committee of the Ministry of Transport on Experimental Work is investigating the case and in conjunction with highway authorities concerned, intends to open up some of the joints and determine: (1) exact position of the concrete beams under expansion joints and how they behave; (2) what subsidence (if any) has taken place at joints; (3) characteristics of concrete where failures have occurred, and also to collect information as to any special features of drainage, height of embankments and flooding.—J. MARIN

WATER WORKS

Water tower in Stoppenberg (Germany) of 70,630 cu. ft. capacity. A. KONRAD. *Der Bauingenieur* (Germany), March 14, 1930, V. 11, No. 11/12, p. 199-202.—Entire structure is made of reinforced concrete. Tank has cylindrical form, 45.9 ft. inside diameter and 44.3 ft. high. Weight of tank (1430 tons) and live load (3300 tons) are supported by 9 inner columns, 2 ft. 5 in. square, and 12 outer columns, 2 ft. 2 in. by 2 ft. 4 in. All columns are connected by vertical stabilizing beams. Foundation consists of 2217 sq. ft. reinforced concrete slab, 3 ft. 3 in. thick. Underground is expected to sink slowly about 6 ft. on account of undermining by coal mine. Walls and bottom of tank are very heavy reinforced to stand high water pressures. Layers of insulating materials were placed inside of tank but were later removed and replaced by "Betonit" insulation, since small leakage of water occurred. Iron portland cement was used exclusively for entire structure. Its tensile strength was 498 lb. per sq. in.—A. E. BEITLICH

Water tower at Hertford. *Concrete Constr. Eng.* (England), Sept., 1930, V. 25, No. 9, p. 505-10.—The structure is situated in a growing residential district and, for this reason, attention was given to the question of appearance combined with economy. It was decided that appearance of a reinforced concrete tower would give concrete advantage over a steel structure. Details of design are given. Floor of tank is 75 ft. above ground level. Capacity is 200,000 gal. A feature of design was the dispensing of horizontal bracing for appearance by increasing size of supporting columns.—J. MARIN

North Bay's new water supply system. W. B. REDFERN. *Contract Record Eng. Rev.*, April 30, 1930, Vol. 44, No. 18, p. 495.—In connection with rebuilding of water supply system of North Bay, Ontario, a new concrete lined reservoir of 4,500,000 gal. capacity was constructed. Reservoir excavated in hardpan and rock is paved with 1:1½:3 mix reinforced concrete 8 in. thick. Lining of one side is supported on concrete buttresses due to insufficient depth of embankment. Bottom is underdrained, with tile lines and is divided into 45 ft. squares, expansion joints consisting of 12 in. copper strips and elastile.—G. M. WILLIAMS

Enlargement of a water tank in Schwaebisch Gmuend (Germany). *Zement* (Germany), April 17, 1930, V. 19, No. 16, p. 386.—Tank, which is 16 ft. high, 80 ft. long and 50 ft. wide has capacity of 1930 cu. yd. and is made of reinforced concrete. Top of tank is Pilz ceiling, and high early strength cement was used for its construction. Ceiling was calculated for load of 32 in. layer of ground and additional live load for tennis courts, which were placed on its top. Special consideration was given to perfect insulation of walls.—A. E. Beitlich

Architectural Design

Church of St. Konrad in Freiburg (Germany). C. A. Meckel. *Zement* (Germany), Aug. 28, 1930, V. 19, No. 35, p. 826-8.—Church is built of reinforced concrete in modern style. It is 65.6 ft. wide, 161.6 ft. long and provides room for 1900 persons. Total interior height is 47.6 ft., that of tower structure is 98.4 ft. Floors consist of concrete slabs, which are specially polished. Roof is vault construction resting on 7 cross beams, with no columns in interior. Use of reinforced concrete throughout makes building fireproof.—A. E. Beitlich

Modern questions of architectural design. "Die Zeitfragen der Architektur." Fritz Schumacher. 1929, Eugen Diederichs, Jena (Germany), R. M. 9.50. Reviewed in *Der Bauingenieur* (Germany), Jan. 3, 1930, V. 11, No. 1, p. 17.—Book belongs to most important publications in field of architectural design of modern structures. Different chapters deal with construction of buildings, bridges, towns and marine structures. Special consideration is given to application of colors in construction practice.—A. E. Beitlich

Field Construction

Bridges

Fourth Ave. viaduct, Moose Jaw, Sask. *Canadian Engineer*, June 24, 1930, V. 58, No. 25, p. 691-692.—To replace a timber trestle, City of Moose Jaw has built a mushroom flat slab viaduct consisting of 30 ft. roadway and two 5 ft. walks with spans of 30 ft. supported on concrete columns. Reinforcing of flat plate slab consists of ½ in. plain bars with a 6 in. spacing in two way mat and diagonal bands with a 3 in. spacing in bottom of plate. Concrete mixture was 1:2:4 by volume using a clean coarse sand and a crushed gravel. Consistency was such that mixture would flow slowly into place with little puddling or jarring. Tests at 34 days showed a strength of 4000 lb. per sq. in. Warm mixing water and ½ per cent of an admixture was used.—G. M. Williams

The Montreal South Shore bridge over the St. Lawrence River. *Eng. and Con.*, Sept., 1930, p. 330-336.—Substructure for South Shore bridge required 62 permanent piers with many types of foundations. A caisson 127 ft. 9 in. by 50 ft. 6 in. by 47 ft. was required for one main pier. Main pier on the city side was founded on two pneumatic caissons carried to rock. It is 47 by 96 by 150 and 200 ft. and contains 18,000 cu. yd. of concrete. River piers are of 2000 lb. concrete and are faced with limestone from a few feet below water level to a few feet above highest ice level. South approach required a number of piers. Ninety-two thousand cu. yds. of concrete were used in the substructure.—N. H. Roy

Concrete arch bridge carries pipe line. F. M. Preston. *Canadian Engineer*, May 27, 1930, V. 58, No. 21, p. 605-606.—Victoria, B. C., has re-

placed an old Howe Truss timber bridge with a reinforced concrete bridge designed to carry two 32 in. diameter steel water supply lines. Crossing 177 ft. long consists of five 16 ft. approach spans and an arch span of 66 ft. with ribs on 7 ft. centers. Arch is of the three hinged type, ribs being precast on their sides of a 1:1:2 concrete mixture and weighing 6½ tons each. Hinges in abutments and at crown consist of brass bushed steel pins turning in cast steel hinges. Approach trestles and abutments on rock were built first and the arch ribs erected by means of a floating derrick. One unit allowed to accidentally drop was recast with quick hardening cement and put in position four days later.—G. M. WILLIAMS

New construction of the Saxon bridge over river Elster in Leipzig (Germany). WESTPHAL. *Der Bauingenieur* (Germany), May 23, 1930, V. 11, No. 21, p. 359-61.—Bridge consists of 12 continuous reinforced concrete beams which rest on two shore abutments and two river piers. Opening between piers is 65.6 ft. and between piers and abutments 54.1 ft. Roadway is 39.4 ft. wide but can be widened to 52.5 ft. Side walks, 19.7 ft. wide are on each side. Larssen steel sheet piling was driven and excavations were made on each river side. One shore abutment and one pier were erected in one excavation. Pile driving was carried out under great difficulties, since underground was very soft. Two pumps were put into operation. Roadway consists of 8.7 in. thick concrete layer with asphalt top. About 24,700 cu. ft. concrete were used for its construction, and abutments and piers consumed 76,500 cu. ft.—A. E. BEITLICH

Quebec bridge roadway construction. JAQCUES JOBIN. *Canadian Engineer*, Aug. 26, 1930, V. 59, No. 9, p. 261-264.—The Quebec Bridge built by the St. Lawrence Bridge Co. and opened to railway traffic in 1917, carries two railway tracks 32 ft. 6 in. center to center, supported on four through plate girders, attached to girder floor beams. Space of 17 ft. 6 in. between interior plate girders was only portion available for roadway purposes. Steel floor beams and stringers attached to the plate girders carry reinforced concrete slab poured in place, which serves as wearing surface of roadway. To allow for expansion and contraction of supporting steel structure, expansion joints of overlapping plate type were provided to permit of a maximum movement as much as 3½ in.—G. M. WILLIAMS

The reinforced concrete arch bridge near Conflans-Fin-d'Oise. O. S. *Zement* (Germany), Aug. 1930, V. 19, No. 34, p. 804-7.—Bridge over river Oise near its junction with Seine river was constructed between March 1928 and August 1929, and was opened for traffic in December 1929. Arch has span of 414 ft. with a height of 55 ft. Cross-section of both arches is rectangular, 6 ft. 10 in. high in center and 4 ft. 2 in. high at abutments. Roadway is 16 ft. 6 in. wide with two 3 ft. 4 in. sidewalks. Vertical columns are spaced about 20 ft. on centers and have octagonal cross-section with 8 in. diameter. Columns are connected with cantilevered transverse slabs on which roadway is built. Latter consists of continuous concrete slab. Arches are hollow for 184 ft. from center on both sides. Wall thickness varies from 1 ft. 2 in. to 1 ft. 6 in. Description of reinforcements and their arrangement is given. Abutments were built upon concrete pile foundations.—A. E. BEITLICH

Handbook for reinforced concrete III. (See ENGINEERING DESIGN—Bridges.)

BUILDINGS

New buildings of the City of Karlsruhe (Germany). OTTO LINDE. *Zement* (Germany), Aug., 1930, V. 19, No. 33, p. 780-2.—Several new structures, including two school buildings, made of reinforced concrete are described. Special consideration is given to modern economic construction methods.—A. E. BEITLICH

Lightweight floors and concrete units in office building. *Concrete*, Sept., 1930, V. 37, No. 3 p. 21.—New type of floor panel—rivet grip steel deck construction—used in erection of 23-story building, has as supporting members steel bar joists, placed in the usual way on principal girders of structural frame and anchored at ends. At midspan a reinforced concrete bridging beam supplies a higher degree of lateral rigidity than otherwise possible. The ribbed steel pans are of 20-gauge metal and provide a solid, leak-proof decking or form for the 3-in. reinforced concrete slab placed over the deck. Exterior walls throughout the building are backed up with Haydite concrete units, standard, half and special size units, totaling 100,000 were used. Absorption test was made as follows on Haydite units and competing material: Four-inch slab of Indiana limestone, representing exterior facing material was placed flatwise in broad and shallow pan of water. Back-up units were then set in mortar, with the thickness of mortar joints between units. Water depth of 2 in. was maintained throughout. Four months later moisture had penetrated both slabs of limestone and the clay tile to practically full height, stopping at level about even with the uppermost shell. Penetration in Haydite units extended from 1 to 1½ in.—C. BACHMANN

Skeleton structures of reinforced concrete. G. RUETH. *Zement* (Germany), July 31 and August 7, 1930, V. 19, No. 31 and 32, p. 728-33, 755-8.—Use of high early strength cement for construction of lower parts of high skeleton structures is recommended in order to decrease dimensions of supporting columns as far as possible. Description of a number of such buildings illustrates application of this construction method for apartment and office buildings, water towers, industrial buildings, hospitals and warehouses.—A. E. BEITLICH

Rapid methods for reinforced concrete construction. WILHELM PETRY. *Der Bauingenieur* (Germany), Jan. 17, 1930, V. 11, No. 3, p. 35-9.—Modern methods for reinforced concrete construction enable erection of such structures with greater speed than was possible several years ago. Great 6-story warehouse in Kiel (Germany), which rests on deep pile foundation was finished in four months although underground work was done under great difficulties on account of high ground water. Addition to paper plant Scheuffelen in Oberlemmingen (Germany) (cf. *Zement* (Germany), June, 1930, V. 19, No. 24, p. 565-7) is 325 ft. long, 80 ft. wide and 68 ft. high. Its construction was delayed by bad weather conditions but was finished in 3 months. Several more examples are discussed and construction methods described.—A. E. BEITLICH

Modern methods and equipment used on American Can building. M. THOMPSON. *Concrete*, September, 1930, V. 37, No. 3, p. 13.—Mixing plant was designed to speed up the handling of both the raw materials and mixed concrete to place 700 cu. yds. daily on American Can Co. building. From bins sand and gravel were delivered to the three mixers by gravity, through weighing and measuring devices. Quantity of water, including any in aggregate, was about 7 gal. per sack of cement in column concrete and 7½ gal. for floor concrete. Proportions were about 1:2:4 for floor concrete and from 1:1½:3 to 1:1:2 for column concrete. Where 2,000 lb. concrete was required, strengths ranged from 4,284 to 4,810 lb. per sq. in. at 28 days. Batches were delivered to a skip at base of hoisting tower, elevated to hopper, then delivered to first of a series of portable belt conveyors, one being 52 ft. long, three each 40, two 37, and one 34 ft. long. Metal forms were used for columns, column heads, drop panels and floor panels. Drop panel forms for flat-slab construction were made in two parts, each containing half the semi-circular opening made by column head. Drop panel forms were supported from the story below by jack frames of 4-by-4 wooden posts and 4-by-6 jackheads, spaced 4 ft. apart. Floor panel forms were rectangular sheet metal panels.—C. BACHMANN

Foundations for library and convention hall of German Museum in Munich (Germany). E. STECHER. *Die Bautechnik* (Germany), March 18, 1930, V. 8, No. 12, p. 197-9.—Museum is located on island in river Isar. Foundations of structures consist of concrete piles. To reach firm stratum 520 vertical shafts were drilled to a depth from 33 to 66 ft. Special movable steel drills were put into operation. Shafts were conically enlarged at bottom. Concreting was carried out with plastic concrete without interuption until ground water level was reached, then upper part of foundations was finished. Concrete piles are connected with horizontal beams on which superstructures are erected. (cf. Hoffmann. *Zement* (Germany), May, 1930, V. 19, No. 20, p. 470-2.)—A. E. BEITLICH

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, Sept., 1930, V. 37, No. 3, p. 27.—In assembling form work for a typical tower, forms are erected one story at a time and thoroughly braced with diagonal braces of 14 x 6 in. material and 3 x 6 in. bracing placed horizontally. Horizontal diagonal wires are twisted across the tower form work just above and below the horizontal 3 x 6 in. bracing. Form work for a story is supported at the corners by "Ell" blocks. Double waling strips serve at main holding members. Waling strips are extended along full length of tower on outer sides when there is only a small offset between face of column and face of wall.—C. BACHMANN

The future of reinforced concrete without forms. G. HOFFNER. *Le Constructeur Ciment Armé*, June, 1930, No. 129, p. 136.—Article urges use of steel and reinforced concrete type of construction conforming to American practice. Standardization of units will permit extensive use of precast units and will eliminate wasteful timber forms, replacing them by standard metal molds. A reinforced concrete building comprising about 12000 sq. yd. of floor area was erected in accordance with this system by Michelin plant at Clermont-Ferrand, the entire job taking only 6 months for its completion. Foundations were finished by end of June 1929, the skeleton and floors by October 1929. About 1200 sq. yd. of floor, including supports and beams, were placed every 10 days. The tests of the finished structure yielded satisfactory results. Other buildings of this type in France are: the auditorium of hotel at Hermitage, hotel Majestic at Clermont-Ferrand and the Renault garages at Saint-Etienne.—M. A. CORBIN

Reinforced concrete structure of new storage and warehouse of the Engelhardt brewery in Berlin (Germany). FR. HERBST. *Zement* (Germany), Aug. 14 and 21, 1930, V. 19, No. 33-34, p. 776-9, 800-4.—New building is located on Lake Rummelsburg near Stralau and was erected from fall 1929 to spring 1930. It is a reinforced concrete skeleton structure, with 96,880 sq. ft. floor area and is 192.3 ft. long and 126.3 ft. wide. Room of 192.3 by 45.9 ft. in basement is taken up by 8 decarbonation tanks with total capacity of 11,000 cu. yds. Total height of building is 98.4 ft. Of special interest is heavy insulation of walls and floors of basement and first floor to maintain constant low temperature. Difficulties were encountered in placing foundation on account of ground water. Foundation is one continuous reinforced concrete slab, is 3 ft. 3 in. thick under 6 and 4-story part of building and 2 ft. thick under 2-story part. Ground water was lowered by means of 20 wells. Basement floor is only a few inches above normal ground water level. Stairways were made of reinforced concrete. Pilz construction was used for ceiling slabs calculated for heavy live loads. Slabs from 8.66 in. to 18.90 in. were supported by square or octagonal reinforced concrete columns, diameters of which increased from 2 to 3 ft. Two concrete mixers delivered material to two distribution towers, 118 and 190 ft. high. Aggregates were transported with dump cars from boat to mixer and cement was added to aggregates in dump cars. Total construction consumed 814 tons high early strength cement, 1360 tons portland cement, 250,000 cu. ft. gravel and 745 tons reinforcing steel.—A. E. BEITLICH

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, August, 1930, V. 37, No. 2, p. 31-34.—Author describes a case where a comparatively thin panel wall of reinforced concrete occupies entire space between wall columns or pilasters, and between the floor slab and wall girder supporting floor above. A stub wall is concreted at the time wall girder and floor slabs are concreted. A key left in top of stub helps to unite it with fresh concrete placed upon it. At top the panel wall forms are held in alignment by U-shaped yokes. Wedges or blocks are inserted between yokes and face of column or pilaster to adjust form work horizontally. The inner and outer panel wall forms are held in proper relation to each other by spreaders and tie bolts and a pair of waling timbers at the top. At the bottom, just above the stub wall, there is another pair of waling timbers, or rangers, made of either single 3-by-4's or of two 1-by-6's or two 2-by-6's. Line drawings show details of form work for spandrel or upturned wall beam itself and how form work is connected with form work for wall column or pilaster. Details are application to a building of flat-slab type of reinforced concrete construction in which window area is to be as large as possible. Since the window extends up to underside of floor slab, the wall space immediately above, between floor slab and window sill, must serve both as a wall and as a girder. Since the spandrel or upturned beam is to be continuous with the floor slab, the inner panel of form work must be left open and unobstructed where slab occurs. Here the form work is supported on small precast blocks of concrete whose height is equal to the depth of slab, these blocks being left in place.—C. BACHMANN

Concrete airship hangar of bold design at Sevilla, Spain. (See ENGINEERING DESIGN—Buildings.)

DAMS

Aggregate for Boulder Dam. *Rock Products*, April 26, 1930, V. 33, No. 9, p. 54-55.—John Mocine, Gen. Sup. of United States Lime Products Corp., San Francisco, Calif., proposes novel method of quarrying large dolomitic limestone deposit for producing the 10,000 tons per day of aggregate that will be needed for Boulder Dam. Method consists in driving tunnel 280 ft. back of and parallel to quarry face. Twenty parallel tunnels are to be driven from the main tunnel to within 40 ft. of the face where each terminates in cross tunnels to be filled with powder. When this is shot a slab 40 ft. thick and height of bank will be brought down. Loading and stemming for next shot can go on without waiting for face to be cleared.—EDMUND SHAW

Transportation methods for raw materials for construction of Grimsel dam (Switzerland). W. FRANKE. *Der Bauingenieur* (Germany), March 14, 1930, V. 11, No. 11-12, p. 192-8.—Site of dam is located about 6000 ft. above sea level and transportation of structural materials was extremely difficult. Cement was delivered by rail to aerial tramway 10.5 mi. long which brought materials to construction site. Dam consists of two sections which are separated by natural rock of Mount Nollen. First section will be 377.3 ft. high and 590.5 ft. wide at its base; 445,000 cu. yd. concrete are necessary for its construction. Second part of dam will consume more than 74,000 cu. yd. concrete. Detailed description is given of aerial tramway and concrete distribution arrangements. Two cable cranes which handle 5600 to 6300 cu. ft. concrete per hr. are used and up to 4,000 cu. yd. concrete were placed in one day. Interesting details of construction of three power plants, connected with dam, are given.—A. E. BEITLICH

Power development on the Magog River at Sherebrooke, Que. VERNON R. DAVIES. *Canadian Engineer*, April 29, 1930, V. 59, No. 17.—Sherbrooke Land and Water Power Co. at Sherbrooke, Quebec, has completed a hydro-power development on the Magog River consisting of a concrete dam,

concrete lined head race canal and power house. Installation consists of 2-900 K. V. A., 2400 volt generators driven by 1100 h. p. water wheels with open flume and propeller type runners. Dam foundation consists of rock from which weathered material was removed and a cut-off trench excavated for the entire length of bulkhead and sluiceway sections. Bulkhead portion is a gravily section having maximum height of about 30 ft. To increase stability dowels, 1½ in. rods 10 ft. long, were grouted 5 ft. into the foundation rock on 2 ft. centers near the upstream face. Tests made to determine effectiveness of these dowels indicated they were of doubtful value. Head race canal 15 ft. wide and 15 ft. deep is lined with reinforced concrete walls 2 ft. thick above the sides of the rock excavation.—G. M. WILLIAMS

Power station Kriebstein near Waldheim (Germany) on river Zschopau. KIRSTEN. *Die Bautechnik* (Germany), March 14, April 4 and 11, 1930, V. 8, No. 11, 15 and 16, p. 149-53, 233-7, 247-50.—Big concrete dam was erected to produce power and to protect low lands against high water. Detailed descriptions of four different projects are given. Site of plant is very favorable in narrow valley of river Zschopau. Bedrock consists mostly of granite with a 9 to 21 ft. top layer of soft yellow loam and sand, which was partly removed. On left hand river bank cement was forced into rock voids to make ground impermeable to water. Quarry, located about half a mile upstream, furnished aggregates of high quality which were crushed in special plant. Dam is of overflow type, 787.4 ft. long and 13.1 ft. wide at its crest, radius of curvature is 73.8 ft. Middle part of dam is built as 85.3 ft. wide weir, top of which is 13 ft. below normal water level of reservoir. Overflow is divided into 6 sections, 22.3 ft. wide, which are separated by six 8.2 ft. wide pillars. Height of dam is 86.3 ft. and it is 66.9 ft. wide at base. Joints were made at distances from 65 to 82 ft., sealed by means of sheet copper embedded in bitumen and asphalt. Great number of thermocouples recorded heat developed in interior of dam. Overflowing water is collected in basin 9.8 ft. deep and 105 ft. long where its force is broken. Floor of basin consists of 6 ft. thick concrete slab with 1 ft. top layer of reinforced concrete. Reinforced concrete bridge designed for load of 40.8 lb. per sq. ft. is built over basin to gates at base of dam. Its span is 114.8 ft. Dam is provided with 3 openings at its base, each 8.5 ft. in diameter and being capable to take in 3355 cu. ft. of water per sec. Gates are operated from top of dam. Three 118 ft. long high pressure pipes lead water to 3 turbines. Diameter of two of those pipes is 7.9 ft., third pipe for small turbine is 5.9 ft. Power station is reinforced concrete skeleton structure with 3 turbines. Structural materials were stored on left hand side of river. Cement, trass and sand were transported by cableway to central mixing plant and silos. Four towers distributed concrete. 1020 cu. yd. was placed daily. Two concrete mixtures, consisting of 440 lb. portland cement and 165 lbs. trass and 396.8 lbs. portland cement and 143.3 lb. trass for 35 cu. ft. concrete were used. Water impermeability of concrete was very much improved by addition of trass. Aggregates consisted of 15 parts sand (0 to ⅛ in.), 15 parts sand (0 to ¼ in.), 41 parts gravel (¼ to 1¼ in.) and 29 parts gravel (1¼ to 2½ in.) Laboratory at site of construction tested strength and water permeability of all mixtures.—A. E. BEITLICH

MISCELLANEOUS

Repairs of Bildwasen tunnel (Germany). K. SCHAECHTERLE. *Die Bautechnik* (Germany), April 25, 1930, V. 8, No. 18, p. 271-3.—Railroad tunnel of 1880 ft. length was badly damaged by water and engine smoke. Rock layer on top of tunnel was partly removed and replaced with concrete filling. New drainage system was built.—A. E. BEITLICH

Guniting sea-water structures. *Concrete Constr. Eng.* (England), Sept., 1930, V. 25, No. 9, p. 521.—Article refers to various wharf constructions to

point out that experience shows importance of ensuring that top surface of the slab be made water tight. Special methods are given with preference to method of applying grout by cement-gun to super structure and under side of the deck. This largely reduces the rusting of the steel reinforcement. Examples given to illustrate the success of the method.—J. MARIN

Construction of coal bin in Duisburg Ruhrort (Germany) with 11,000 tons capacity. HEINRICH BUTZER. *Der Bauingenieur* (Germany), March 14, 1930, V. 11, No. 11-12, p. 190-2.—Coal silo structure consists of 32 cells; it is 367.5 ft. long, 45.9 ft. wide and 55.8 ft. high, with capacity approximately 11,000 tons. Cells are provided with conical bottom, 22 (for coarse coal) show an angle of 50 degrees and 10 (for fine coal) are built with angle of 65 degrees. Unfavorable underground conditions made foundation on reinforced concrete piles necessary. Entire structure is divided into 3 parts by 2 expansion joints.—A. E. BEITLICH

Successful transit mix concrete. R. M. BELL. *Rock Products*, June 7, 1930, V. 33, No. 12, p. 109.—Brief description of operation of Swigert, Hart and Yett, Portland, Ore., where portable charging plant was introduced to shorten the haul on a 60,000 yd. job. Not many details are given.—EDMUND SHAW

Winter construction. A. SUTTER. *Der Bauingenieur* (Germany), March 7, 1930, V. 11, No. 10, p. 160-3.—Best way to make construction work possible during severe cold weather periods is to protect whole structure against cold outside air. Then the temperature can be kept within normal range by heating with hot air. Raw materials must be preheated. Addition of anti-freezing agents to concrete is not advisable, since this mostly causes considerable loss in strength. From economic view point winter construction must be highly recommended. Costs for heating and protecting amount to only a small fraction of wages, and work is provided for laborers during cold weather seasons.—A. E. BEITLICH

Notes on concrete and reinforced concrete made on trip through United States of America to Eastern Asia. E. PROBST. *Der Bauingenieur* (Germany), March 14, 1930, V. 11, No. 11-12, p. 180-6.—Author gives his impressions gathered on trip through U. S. A., Japan and China. He discusses modern American methods for concrete road and dam construction, use of lightweight concrete and application of concrete for railroad construction jobs. Economic conditions for cement and concrete in Japan and China are characterized and their new standard specifications and methods are criticised.—A. E. BEITLICH

Construction of a waste water sewer pipe system under river Rhine near Koeln (Germany). OTTO WERKEN. *Die Bautechnik* (Germany), March 7, April 18 and May 2, 1930, V. 8, No. 10, 17 and 19, p. 137-9, 261-4, 285-8.—Increasing population of city of Koeln made construction of new sewage disposal plant necessary. New structure is located on right side of river Rhine. Sewage from old plant on left side had to be led underneath river to new plant. Two sewer pipes, 6.1 ft. and 3.1 ft. in diameter, capable of carrying 425 to 450 gal. of water per hr., were built in one single concrete body. Pipes having total length of 1119 ft. were laid in excavation in river. Connections were made under water by means of diving bells. Detailed description of interesting placing method and several illustrations are given.—A. E. BEITLICH

Tall concrete chimney construction. *Canadian Engineer*, June 17, 1930, V. 58, No. 24, p. 683-684.—A concrete chimney 422 ft. 6 in. high and 8 ft. in diameter has been erected by the Horne Copper Corporation, Noranda, Quebec. Base on solid rock consists of a concrete ring 7 ft. 6 in. deep, 35 ft.

outside diameter and 23 ft. inside diameter, reinforced top and bottom with rings of 1 in. bars and ¾ in. radial bars. Concrete shaft was designed to resist combined loading of its dead weight and a wind pressure of 25 lb. sq. ft. of projected area. Connection of shaft to base is made by means of 206 1 in. steel dowels and shell is reinforced by both vertical and horizontal steel. To withstand acid action of gases stack is lined with a 4 in. acid resistant, vitreous brick laid up in special acid proof mortar, built in 45 ft. sections supported on ledges which are protected by a lead flashing where exposed. In addition inside surface as well as the outer 100 ft. of the concrete surface of the shaft is covered with an acid resistant bitumastic paint. Concrete mix for base was 1:2:4 cement, sand and gravel and for shaft a 1:2:3, with average slump of 6 inches. Adjustable all steel forms supported by an interior scaffold were used.—G. M. WILLIAMS

American foundation methods. H. GRIESEL. *Der Bauingenieur* (Germany), Feb. 7, 1930, V. 11, No. 6, p. 91-6.—First part of article describes foundations with wooden piles, concrete piles, reinforced concrete piles, Raymond piles and combinations of wood and concrete piles. Advantages of Raymond piles are especially characterized. Pile driving and necessary equipment are illustrated, and examples of practice are shown. Second part deals with caisson methods. Caissons can be placed either by excavating or by means of compressed air. Foundation job during construction of Delaware bridge between Philadelphia and Camden is described with dimensions and detailed graphs. Construction of Holland tunnel under Hudson river is example of foundation with compressed air method. Several foundations of skyscraper buildings are illustrated.—A. E. BEITLICH

Winter concreting methods applied on contract of moderate size. ROBT. C. JOHNSON. *Concrete*, Oct., 1930, V. 37, No. 4, p. 13-16.—Concrete plant on 4,000 cu. yd. job of wall-bearing design was limited to concrete mixer. Responsibility for quality depended upon competent men and mechanical controls were eliminated. Aggregates were measured by wheelbarrow, and 8 to 10 test samples were taken daily. Proportions were 1:2:4. One man was detailed through winter months to take three test cylinders from each sample of concrete, to be broken at customary periods, and to keep temperature records. Specifications contained two clauses: temperature of 60 to 80° for concrete being poured, and that freshly placed concrete be kept at minimum of 70° for at least five days after concreting. Following equipment was used for protection: Vertical steam boiler with 100 lb. pressure capacity; 150 lin. ft. steam hose, about 100 salamanders, canvas, 10,000 sq. ft.; Sisalkraft, 20,000 sq. ft. Total cost of material used directly for winter work and winter work labor costs amounted to about $1.04 per cu. yd. of concrete placed on the entire job.—C. BACHMANN

Remarkable foundation jobs during construction of railroad Jungfernheide-Gartenfeld in Berlin (Germany). MAX JUSSEL. *Die Bautechnik* (Germany), January 24 and February 7, 1930, V. 8, No. 4 and 6, p. 45-8, 74-7.—Railroad crosses suburban tracks on bridge of 196.8 ft. span. Abutments show very interesting construction. Unfavorable underground conditions made very deep foundations necessary. Chemical analysis of ground water showed presence of aggressive and corroding substances. Abutments were founded on caissons, made of high early strength reinforced concrete, 1:1.5:3 mix. Concrete of normal cement in 1:2:6 mix was used for construction of base of abutments. All parts exposed to ground water were protected by wall of acidproof bricks, cemented with high quality cement mortar (1:2). Three inner walls divide each caisson into 6 cells. These walls were provided with openings. Excavated material was brought out by two elevators. Con-

crete from mixer of 13½ cu. ft. capacity was distributed by tower and dump cars. Plastic concrete was used for caisson construction. Hardened concrete was very dense. Placing of caissons took 17 days at rate of approximately 6 ft. per 24 hours.—A. E. BEITLICH

Reinforcing structures with gunite. J. F. SALMON. *Canadian Engineer*, Sept. 2, 1930, V. 59, No. 10, p. 281-283.—The Canadian National Railway has made use of gunite to protect and prolong the life of structures which would otherwise have required replacement at high cost. Disintegration of Mount Royal tunnel at Montreal resulted in high maintenance cost as well as danger to traffic due to falling rocks. Using no reinforcement a ¾-in. coating of gunite was applied to interior at a cost of $30,000, since which time all trouble has been avoided with no cost for maintenance. Brick piers in the Humber River bridge at Weston, Ont., were disintegrating and it was decided to replace them at an estimated cost of $500,000, after an earlier attempt to retard disintegration by guniting directly into the brick surface, which was not successful. The old gunite coating and all loose material was removed, joints raked out and surface sand blasted. Metal fasteners were grouted into the joints and reinforcement consisting of rods, angle irons and a 2 in. x 2 in. No. 8 wire mesh were attached with a space of 1½ in. between reinforcement and face of pier, after which gunite was applied. Cost of Weston job was $60,000. Repair of Cap Ronge viaduct, Quebec, at a cost of $70,000 saved rebuilding at a cost of $2,000,000. Concrete piers of Blende River viaduct were repaired with gunite for $65,000, thereby postponing a replacement charge of $1,000,000. All these repairs were made without interference with traffic.—G. M. WILLIAMS

Construction of the German waterway commission (Reichswasserstrassen Verwaltung) in 1929. GAEHRS. *Die Bautechnik* (Germany), January 10, 24, February 7, 21, 1930, V. 8, No. 2, 4, 6 and 8, p. 21-5, 48-52, 78-82, 114-8.—Comprehensive article describes new construction, enlargements and repairs of ship channels, locks, power stations and harbors in Germany including following concrete and reinforced concrete structures: (1) lock Anderten near Hannover, (2) highway bridge near Peine with 190.3 ft. span, (3) abutments of 278.9 ft. railroad bridge Peine-Braunschweig, crossing Mittelland channel at angle of approximately 41 degrees, (4) three-hinged reinforced concrete arch bridge near Meerdorf with 157.5 ft. span, (5) sewer systems near Aue and Allen consisting of high pressure concrete pipes with 2 openings of 40.4 sq. ft. and 3 openings 12.79 ft. square, (6) new locks in river Weser, main lock being 738.2 ft. long and 41.0 ft. wide, and (7) 7 locks in the river Neckar. Concrete used for all these structures was made from low lime portland cement, since ground water had corroding action.—A. E. BEITLICH

Use of under-water cast concrete in Sweden. F. TRIER. *Die Bautechnik* (Germany), February 21 and March 7, 1930, V. 8, No. 8 and 10, p. 109-12, 142-4.—Methods of under-water casting of concrete are described. Process can be carried out (1) with pipes, (2) with caissons, (3) by pouring and (4) by pressing cement mixtures. Best mixtures of concrete for pipes, movable in vertical direction, range between 1:2.5:3 and 1:4:5 (cement, sand, gravel). Caisson method requires mixtures from 1:2:4 to 1:3:4. Bridge over Skellefte river was built by pipe method. Concrete was poured in layers 1 ft. thick and 3 ft. wide, special care being taken to prevent concrete from sinking in pipe below water level. Concreting was continued through 3 days and 3 nights. Caisson method was used for construction of foundation of one pier of Klara bridge in Stockholm. Methods (3) and (4) can be used only when water is not very deep. Laboratory tests were made to study effect of working, consistency and proportioning of mixture and composition of aggregates. Results showed that concrete cast under water is influenced much more by above factors than ordinary concrete. Proper consistency must be maintained. Cement content

must be higher than for ordinary concrete to obtain same strength. Percentage of fine material should be slightly greater than indicated by Fuller curve. Formation of mud must be prevented by continuous pouring. Numerous construction jobs are described, illustrating applications of above methods. More detailed description is given of construction of coffer dam in Beckholmen (Sweden), and quay near Wallvik (Sweden). (cf. W. Nakonz. *Die Bautechnik* (Germany), Jan., 1930, V. 8, No. 3, p. 35-6.)—A. E. BEITLICH

Waterproofing of concrete structures. H. R. LORDLLY. *Contract Record Eng. Rev.*, April 16, 23 and 30, 1930, V. 44, No. 16-17-18.—Methods of waterproofing concrete structures has not kept pace with increased use of concrete. Experience has shown that the old idea of "a little more cement in mortar or a richer finish" does not give satisfactory results. In a review of waterproofing, four classes of structures are involved: (1) heavy structures exposed to high heads of water, such as dams; (2) lighter structures such as reservoir walls which may be waterproofed by using membrane near water side of wall or by use of admixture; (3) unit pieces of artificial stone or concrete waterproofed during manufacture with an admixture and (4) foundation walls in contact with wet soil which can be protected by tarring or asphaltic paint. Requirements for a perfect membrane waterproofing include flexibility, elasticity, toughness and tensile strength of fibre and ability to absorb and retain material used to saturate membrane fibres. Pointers on waterproofing basement floors, basement or cellar walls, concrete roof, waterproofing by admixture, surface waterproofing and surface waterproofing with impregnating solutions are included. Deductions from experience in placing sub-aqueous concrete through spout or tremie are summarized.—G. M. WILLIAMS

A new construction principle. GEORG EHLERS. *Der Bauingenieur* (Germany), Feb. 21, 1930, V. 11, No. 8, p. 125-32.—Construction of coal bin with capacity of 140,000 cu. ft. shows application of new principle in reinforced concrete construction practice. Structure is 197 ft. long and 32.8 ft. wide and consists of 8 single cells, each 31.2 ft. high. Total height of structure is 75.9 ft. It is supported by 2 single frames at the ends and 3 pairs of double frames under bins. Dimensions of columns of double frames are 2 ft. 9 inches by 4 ft. 3 inches, those of single frames are 2 ft. 6 inches by 4 ft. 3 inches. Distance between columns of double frames is 8 ft. End and double frames are placed 42.6 resp. 43.9 ft. apart. Main feature of structure is complete lack of stabilizing beams and girders. Walls 8 in. thick and bottom 10 in. thick are unsupported over about 42 ft. and only their unique connection and joint compensation of certain stresses made construction possible. Mathematical calculations on which construction was based are fully described. (cf. H. Craemer, *Zement* (Germany), July 24, 1930, V. 19, No. 30, p. 703-8.)—A. E. BEITLICH

Winter jobs in concrete and reinforced concrete construction. WILHELM PETRY. *Der Bauingenieur* (Germany), March 14, 1930, V. 11, No. 11/12, p. 175-9.—Author describes a number of winter jobs: construction of monolithic reinforced concrete stack, 262.5 ft. high, for ammonia plant in Merseburg (Germany), foundations for asphalt plant, reinforced concrete building for filtration plant, upper stories of a big warehouse in Leipzig (Germany), two new plant superstructures and enlargement of big hospital in Muenster in Westfalen (Germany). Experience, with those structures lead author to following suggestions: High alumina cement is used with advantage due to high heat of reaction which is generated during setting process. Materials must be preheated and least amount of water should be used for mixing concrete. Reinforcements and formwork must be cleaned from ice and snow. Working and placing of concrete should be made in rooms, which are protected

against frost. After placing, concrete must be covered with canvas, straw or other similar materials, especially over night, or can be directly heated by means of coke burners.—A. E. BEITLICH

Damming, blowing and sealing in crib house construction. CHAS. C. MOODY. *Concrete*, Aug., 1930, V. 37, No. 2, p. 13-16.—In building the crib house, or tunnel terminus, for the water intake on a large power house construction job in Illinois, novel method of driving 14 in. interlocking sheet piling was involved. In order that the sheet might go down straight into the ground the first pile was driven but 10 ft. Another was started and driven 8 ft., another 6 ft., and another 4 ft., and the last 2 ft. Then the hammer was started again on the first, and each one driven 2 ft. more. The steel sheeting was but 12 in. from the building at top and in its driving the piling had a tendency to go toward the building, leaving 9 in. in which to work at bottom. Depth of excavation was about 33 ft. below top of sheeting. With specially devised pipes and air hose, only a very short time was required to remove all sand and stones to the depth required. The slot, between steel sheet piling and old foundation was sealed by concrete placed through an 8 in., 16 gauge galvanized sheet tube 25 ft. long with lower end sealed. When the pipe was full, it was slowly raised to release wood seal at bottom and operation continued until concrete in slot formed a layer 4 ft. thick. When excavation in cofferdam had proceeded to approximately same elevation as seal on opposite side of sheeting, water was let out of slot by burning a hole in steel sheet just above the concrete level.—C. BACHMANN

ROADS AND PAVEMENTS

Modern European developments in road construction methods. E. NEUMANN. *Die Bautechnik* (Germany), Feb. 14, 1930, V. 8, No. 7, p. 90-4.—Development of modern road construction methods in Europe, especially in France and Italy, is described. Special consideration is given to concrete roads. —A. E. BEITLICH

Old Pavements embedded in widened highways. *Concrete*, Sept., 1930, V. 37, No. 3, p. 17.—Design worked out salvaged old 18 ft. pavement laid 8 years ago on National Old Trails road out of Indianapolis and consisted of two thickened edge slabs 10 ft. wide and the resurfaced center portion. Resurface has minimum thickness of 5 in. over old pavement and additional foot on each side is 9 in. thick. Reinforcement placed over center portion only, consisted of an assembled bar mat of ½ in. square deformed bars. Transverse bars were 20 ft. 10 in. long with ends bent around 180 deg. for anchorage. Two construction joints were provided where the side slabs join the center portion, and a longitudinal dummy joint 1½ in. deep and ¾ in. wide down center of middle section.—C. BACHMANN

Concrete road construction in Germany. "Betonstrassenbau in Deutschland." RIEPERT. 1929, 311 pp. Zementverlag, Charlottenburg (Germany), R. M. 4.80. Reviewed in *Zeitschrift des oesterreischischen Ingenieur und Architekten Vereins* (Austria), April, 1930, V. 82, No. 15-16, p. 136.—Technical development in concrete road construction during the recent years is described. Standard specifications for road construction and construction materials are discussed.—A. E. BEITLICH

Cement and bitumen for concrete road construction. WALTER OBST. *Teer und Bitumen* (Germany), July, 1930, V. 28, No. 19, p. 315-6.—Concrete which is made with an addition of tar or asphalt emulsions to mixing water is

excellent road material. These additions do not lower cementing properties or strength of cement. Blast furnace slag cement is especially suited for this purpose. Discussion is given of several American, French and Swiss patents and construction methods are described.—A. E. BEITLICH

Concrete roads in the Elbe river region near Hamburg (Germany). ADOLF WIESE. *Die Bautechnik* (Germany), Feb. 1930, V. 8, No. 7 and 14, p. 106-8, 221-3.—A number of new concrete roads are described. Article includes details of interesting construction methods.—A. E. BEITLICH

Concrete and asphalt road surfacing. R. E. CLARKE. *Cont. J.* (England), June 4, 1930, V. 102, No. 2660, p. 1819.—Variation in length of road slabs is caused by contraction during hardening amounting to ⅛ in. in 50 ft., expansion and contraction due to temperature change, causing ¼ in. in 50 ft. for 80° F. variation, and a much smaller change in length due to alternative wetting and drying. Tensile stresses which depend on length of slab, and friction between sub-base and concrete, cause cracks which may be localized by expansion joints. Such joints are weak points due to (1) weakening of bearing value of sub-base from penetration of water, (2) relative vertical displacement of concrete, (3) impact shock at uneven joints, (4) concentrated load at end of slab. These joints may be strengthened by raising bottom reinforcement to near surface, or by building independent supporting slab under ends of main slab. Longitudinal expansion joints may be used as "white lines" and studs inserted at important junctions; and transverse joints made to break joint at 50 ft. intervals. Expansion joints left proud and burnt down with hot iron tend to become damaged by traffic. Low joints grouted with Mexphalt are recommended, joint being dried with blow torch to save time, if necessary. Joint composed of cork and bitumen is now obtainable and is claimed to have power of expansion and contraction without protrusion. Goldbeck's experiments show that coefficient of friction between slab and average sub-base may reasonably be taken as 2. From this and assumed allowable tensile stress on concrete of 50 lb. per sq. in., 8-inch slab should have joints every 48 ft. Rough surface concrete has been successfully obtained by using 2 in. granite as coarse aggregate for top course. Well tamped concrete was brushed with thick brush without disturbing aggregate until laitance was removed to depth of ¼ in. It is important to see that aggregate is properly exposed or surface becomes smooth under traffic. Elsewhere matrix has been laid for top course and coarse aggregate afterwards laid on top. Heavy tamping is required and the surface is not so level. Finished surfaces were covered with waterproof canvas on frames to protect from sun rays and winds, and when safe, sprayed with water and covered with 2 in. of continually wetted sand, for four days for "ferrocrete" and 14 days for portland cement. Before traffic was allowed over, the surface was swept and washed and treated with a 25 per cent solution of silicate of soda in three applications. It is thought that hydrate of lime liberated during setting is converted into silicate of lime which is a hardener. Average output with gang of 24 men (including a man checking level of channels) was 280 sq. yd. using a Millar mixer 14 L, which gave 30 per cent over its rated capacity of 14 cu. ft. unmixed. Importance of using first class materials and watching water-cement ratio is stressed. No advantage beyond bringing to the surface a laitance of drowned cement is obtained by tamping a too wet concrete. Care should also be taken to see that sub-base is sufficiently saturated with water before depositing slab, or moisture from concrete will be absorbed and cracks formed. It is also found that cement and fine aggregate are drawn away from surface.—JOHN E. ADAMS.

Roads and road making. *Irish Builder Eng.*, (Ireland) Aug. 30, 1930, V. 72, No. 18, p. 774.—Experiments in connection with design and construction of con-

crete roads and foundations. 3 miles long, 30 ft. wide, formed on a ballast bank varying in depth from 2 to 20 ft. An 8 in. reinforced concrete slab was laid on a 4 in. consolidated bed of clinkers and the surfacing was 2 in. stone filled asphalt mat. The bays of concrete were 14 ft. 6 in. long and full width of road. At every fourth transverse joint, bituminous sheeting was inserted for expansion, and a 12 in. by 8 in. concrete beam was formed under the joint. The mix was 1:2:4 and the reinforcement 4.7 lb. per sq. yd. The road carries 10,000 tons daily and has been used for two years. No defects were observed during the first year but cracks developed later at 14 ft. 6 in. intervals or multiples, obviously where joints in the foundation occurred. The position of the cracks in the asphalt are such as to show that heavy vehicles depress the edge of slab below level of those they are approaching. It is found too, that the slabs twist upwards and downwards as the temperature varies, and that contact with subsoil may be lost at edges during some periods. Interlocking joints would appear to remedy these defects and the subject is being investigated by Ministry of Transport.—JOHN E. ADAMS

Keeping ahead of the times in paving practice. *Concrete*, August, 1930, V. 37, No. 2, p. 22-24.—Continual effort on the part of engineering department and contractors to take advantage of all betterments and to pioneer in methods is evident in quality of concrete pavement placed in Bethlehem, Pa. Crushed and washed limestone screenings or chips are used as fine aggregate. This material was adopted because of its considerably lower price and because it compared favorably with Ottawa sand. Its use has resulted in increased compressive strengths in test cylinders and pavements. Absorption tests made from time to time are closely supervised and conducted under laboratory conditions. Slab now laid is uniform 7 in. thick and feature of design is use of thickened edges along car track areas, manholes, etc. Thickened edge is not used along curb and gutters or longitudinal joints. Pavements are divided longitudinally for traffic guidance and to facilitate laying. Longitudinal joints are made with deformed plate. Dowels are spaced at 3 ft. intervals. No dowels are used in transverse joints. A deformed metal plate carries a premolded filler. Plate is pointed with hot asphalt and filler pressed on with road roller.—C. BACHMANN

Quebec bridge roadway construction. See FIELD CONSTRUCTION—Bridges.

WATER WORKS

New McTavish pumping station, Montreal, Que. C. J. DESBAILLETS. *Contract Record Eng. Rev.*, April 2, 1930, V. 44, No. 14, p. 385.—McTavish Pumping Station, rebuilt and enlarged by Montreal Water Board, together with reservoir serving high level portions of the city is of Scotch baronial style of architecture to conform with nearby buildings of McGill University. Exterior is of random ashlar limestone and reinforced concrete frame with footings in solid rock. Floor slabs are 4 in. to 6 in. thick except around conduits where 8 in. of concrete is used as filler with 1½ in. of cement mortar finish. Reservoir is excavated in solid rock but to reduce seepage, bottom is paved and side walls waterproofed. Pavement consists of 6 in. concrete slab, reinforced with "Steel crete," divided into panels 20 ft. x 30 ft. with ⅞ in. Minwax expansion joints. Pavement was carried five feet up side walls with remainder of walls coated with gunite. Pavement 20 ft. wide has been placed outside retaining walls at top to intercept surface water from higher ground.—G. M. WILLIAMS

Enlargement of water tank in Schwaebisch Gmuend (Germany). (See ENGINEERING DESIGN—Water Works.)

North Bay's new water supply system. (See ENGINEERING DESIGN—Water Works.)

Reinforced steelwork tower, Harpenden. *J. Institution Municipal County Eng.* (England), Sept. 2, 1930, V. 47, No. 5, p. 262.—Steelwork in a 350,000 gallon capacity water tower, 85 ft. high forms a rigid, pre-erected steel structure designed to carry the dead weight of the temporary centering and wet concrete. No scaffolding is required, centering being suspended from the steelwork. In this case, when steel is initially stressed by the dead load, and before the concrete sets round it, a higher working stress is permissible for watertightness. To avoid irregular cracks, the planes of stoppage in concreting were predetermined, and joints grooved in the water face and pointed with an elastic compound. No waterproofing compounds were added and tests showed efficient watertightness. The tank is carried on three circles of columns, containing 12, 12 and 6 columns respectively, all suitably braced radially and circumferentially.—JOHN E. ADAMS

SHOP MANUFACTURE

How products manufacturers may increase business volume. AUSTIN CRABBS. *Concrete*, August, 1930, V. 37, No. 2, p. 17-19.—From the writer's own business experience it is his belief that a products manufacturer may logically and profitably become a dealer within following limitations: (a) He may be a jobber (or a manufacturers' agent) for various concrete specialties not made at his plant. (b) He may be the manufacturers' agent for incombustible building specialties other than concrete products. (c) He may deal in so-called permanent building material specialties in common use but which may not be sold by other local dealers to any great extent. Products manufacturer is supposed to be equipped to make and sell materials to be bought and used by contractors in construction. If he undertakes to enter contracting business as sideline he will be competing against very contractors to whom he hopes to sell some of materials he manufactures.—C. BACHMANN

New dry paint for the concrete brick industry. BELANI. *Zement* (Germany), July, 1930, V. 19, No. 29, p. 690.—New Paint is prepared from iron ore of high purity from Kaernten (Austria) which contains up to 94 per cent Fe_2O_3 and Fe_3O_4. It is ground to fineness of 2 per cent residue on sieve with 6400 meshes per cm.^{2} Paint is absolutely weather- and fade-proof. SO_2 and H_2S have no effect and it stands temperatures up to 160° C. without darkening.—A. E. BEITLICH

MATERIALS

ADMIXTURES

Diatomite as concrete admixture material. ELLIOTT S. HASTINGS. *Rock Products*, Aug. 2, 1930, V. 33, No. 16, p. 55.—Representative diatomites were selected for a series of tests, all other materials being uniform. It was found that increase in compressive strength varied with alumina and iron oxide contents of the diatomites, a table showing increases from 16 per cent to 28 per cent in compressive strength with additions of 3 per cent diatomite which varied from 2.40 per cent to 17.86 per cent alumina and iron oxide. Author says he has never found a loss of strength from addition of any diatomite, all cases reported being found due to conditions of mixing and pouring. Reduction of laitance and efflorescence has been found proportional to silica present. Amorphous silica present presumably combines with lime liberated from cement thus reducing efflorescence, and absorptive power of diatomite prevents laitance. There appears to be a definite relation between lubricative effect, or workability added by diatomite, and shape of particles. Photomicrographs and chemical analysis are given for various dolomites used in the strength tests. It is considered a matter of economics whether the desired strength should be secured by the use of the proper amount and type of diatomite or regulation of the water-cement ratio.—EDMUND SHAW

AGGREGATES

Breeze and clinker concrete. *Engineering* (England), July 11, 1930, V. 130, No. 3365, p. 41.—The British Department of Scientific and Industrial Research has issued Special Report No. 15 dealing with corrosion of steel by breeze and clinker concrete. It was found, generally speaking, the corrosive power of concrete increases with increasing sulphur content of the aggregates, and that sometimes even a small amount of sulphur left in well vitrified clinker will provide rusting. The extent of this action is reduced when fines in clinker aggregate is replaced by sand. Rusting may occur under dry indoor conditions. It is recommended that safe practice requires the use of coal residue of any kind as aggregates to be forbidden in concrete if the material is to come in contact with steel when in use.—G. M. WILLIAMS

Use of sand from dunes for concrete structures in sea water. A. GUTTMANN. *Bautenschutz* (Germany), March 20, 1930, V. 1, No. 1, p. 6-10.—Fact that many failures of concrete structures in sea water occurred when sand from dunes was used, was investigated and it was found that sand from dunes has 26.1 per cent more voids than normal river sand. Strength tests were made with regular and dune sands. In order to obtain same density with dune sand, 23.6 per cent more cement was required. Dune sand is suitable for sea water structures, when used in rich mixtures. Latter can be made normal, when concrete is allowed to harden in air before placing in water.—A. E. BEITLICH

The bulking properties of microscopic particles. PAUL S. ROLLER. *Ind. Eng. Chem.*, Nov., 1930, V. 22, No. 11, p. 1206-8.—By means of an air analyzer for fine powders, an anhydrite, gypsum, portland cement, and chrome-yellow powder were separated into homogeneous fractions above 1 micron surface mean diameter. The bulkiness, or volume per unit weight, was found to increase with decrease in particle size below a critical diameter; for particle sizes greater than the critical diameter bulkiness was constant. For all powders the same functional relationship was found to hold between voids per gram and surface mean diameter. The differences in the value of the constants for the different powders appear to depend chiefly on the particle shape, whether

cubic, prismatic, basal, etc. As would be expected from a consideration of packing of small particles in voids of larger particles, surface mean diameters of portland cement and chrome-yellow microscopic powders calculated from the bulkiness of the powder were found to average several tenths of a micron higher than true mean diameters. With this correction in mind, for powders above 1 micron surface mean diameter, a rapid method presents itself of estimating the mean particle size of the microscopic powder from a knowledge of its curve of bulkiness vs. particle diameter, but no knowledge as to distribution of particle sizes in the powder is thus obtained.—ROY N. YOUNG

Flexibility. Aim of this crushed stone operation. *Rock Products*, Aug. 30, 1930, V. 33, No. 18, p. 33.—New plant of the Elmhurst-Chicago Stone Co. replaces two old plants. Outstanding features are: A carefully worked out spout arrangement permitting any mixture of sizes or sending sizes to be recrushed; the use of vibrating screens for both scalping and sizing; the use of conveyors instead of bucket elevators throughout; a surge or equalizing bin and a variable speed feeder to control the flow of the stone to the screening plant; starting and stopping of all screen house equipment from one of several conveniently located push buttons; safety device in surge bin to give warning when the bin is nearly full and to stop conveyor when it is full. Only steel and concrete are used in construction. A concrete products plant is operated and the office and some other buildings are made from its product. An unusually complete machine shop is included.—EDMUND SHAW

Aboard a lake-going sand and gravel plant. *Rock Products*, Sept. 13, 1930, V. 33, No. 19, p. 41.—Sand and gravel dredge Brazil of the Marine Dredge and Gravel Co., Chicago, makes sand for fine concrete aggregate by a double classification. The sand is pumped by two 18-in. pumps, each supplying its own screening and classifying unit. Stream goes first to a large tank classifier which overflows about one-half of the solids, which is unwanted fine sand. After passing a screen to take out gravel the sand and water go to a surface current classifier with three spigots. These discharge three products, coarse, medium and fine. Any part or all of any one of these may be wasted and by mixing the required amount of each the grading may be kept constant. —EDMUND SHAW

Standardizing aggregate sizes in Los Angeles. HARRY D. JUMPER. *Rock Products*, April 12, 1930, V. 33, No. 8, p. 65.—As many as 22 sized aggregate products were formerly sold in Los Angeles, each having a different trade name. After a merger of larger companies 11 products were made standard. The aggregates used for cement concrete have been designated as "gravels" and the aggregates for bituminous pavements as "crushed rock" although both are largely crushed gravel and boulders. The sizes for concrete range from No. 1, 2½ to 1½-in. to No. 4, ½-in. to 10 mesh. Gravel No. 123 is a mixture of sizes from 2½-in. to ¼-in. This is not used as much as formerly, practice being to deliver separated sizes to job, thus avoiding segregation.—EDMUND SHAW

An independent study of aggregate characteristics. LEROY C. GILBERT AND H. F. KRIEGIE. *Rock Products*, June 21, 1930, V. 33, No. 13, p. 58.—Following their investigations on gradation and voidage these authors describe an investigation into comparative merits of gravel, stone and slag as concrete aggregates. Investigation takes in not only their own tests but those of Kellerman of the Bureau of Public Roads and of Walker and Proudley. Mixes were made for a constant mortar-voids ratio and cement content was checked by analysis. Differences in compressive and transverse strength were finally ascribed to poor gradation, the weak concrete being deficient in the ¼-in. to ¾-in. particles. This was checked by specimens which had these sizes in

excess and those having just the amount to make a smooth distribution curve. The distribution curve is a form of direct plot of sieve tests in which each sieve is represented by a vertical line. The height of a point on any line represents the percentage remaining on the sieve it represents. Points are connected to form a curve. Horizontal spaces between the vertical lines have no value. Gap gradings and excess of any size show up better than with other plots. The authors conclude that any notable differences in the concrete making quality of the aggregates tested must be ascribed to inferior gradation where they cannot be ascribed to differences in cement content or mortar-voids ratio. It is suggested that different gradations of sand might sometimes be specified for stone than for gravel, the stone (or slag) with high voids requiring a coarser sand. The most efficient combined aggregate was found to have from 21 per cent to 29 per cent of 10-mesh to ¾-in. material. Differences of 10 per cent in strength can result more easily from changed gradation than from a change from one type of aggregate to another. Until our present conception of fine aggregate as ¼-in. to 0 changes we must supply the intermediate material with fine material in the coarse aggregate.—EDMUND SHAW

The missing link in aggregates. LEROY C. GILBERT AND H. F. KRIEGE. *Rock Products*, June 21, 1930, V. 33, No. 13, p. 55.—The authors review the work of Goldbeck and Smyers on the relation of gradation to voids and carry it further in their own investigations. They show the relation to be: (1) The more nearly uniform the size of particles in an aggregate, the greater is the voidage. (2) When two aggregates of the same general shapes but of different sizes are combined in several proportions, the greatest void reduction occurs with approximately 50-50 per cent combinations. (3) The more widely the two fractions to be combined differ in size, the greater is the void reduction. Thus a mixture of approximately 50 per cent 2-in., 1½-in. aggregate with 50 per cent below 200-mesh material is the densest observed mixture of any two separates between these two extremes. (4) As the "gap" between coarse and fine aggregates is increased, voidage of each portion increases while voidage of combined portions decreases. Thus the separate portions 2 in., 1 in. and 28 to 100-mesh particles have higher voidage than 2 in., ½ in. and 8 to 200-mesh particles respectively. However, the voidage of the 2 in., 1 in. and 28 to 200-mesh sizes combined is less than that of the 2 in., ½ in. and 8 to 200-mesh sizes combined. (5) When more than two fractions are mixed lowest voidage results from combination which provided sizes of particles just fitting into the voids of each larger fraction or combination of fractions. With spheres of unit diameter the next smaller separate which can be used to just fit without crowding into the interstices is 0.414 units in diameter. Authors conclude that low density mixtures are not best aggregates on account of their "gap grading." Most complete aggregates are short in ½ in. to ¾ in. size.—EDMUND SHAW

Promotion of premium aggregates. STANLEY M. HARDS. *Rock Products*, Aug. 16, 1930, V. 33, No. 17, p. 70.—Opinion is expressed that engineers are beginning to discriminate among concrete aggregates, and producers will do well to investigate their products and reprocess if necessary. Adoption of trial method of designing mixes encourages the practice of discrimination. The author gives California highway practice in the design of concrete mixes. Trial mixes are made with a definite oversanding of the voids in the coarse aggregate, the cement being fixed. Weight proportions are converted by volume to give yield. With the cement and water fixed, workability can be secured by changing the sand grading, by changing the sand proportion and by changing grading and proportion. Experience shows that sand for maximum workability with minimum water ratio will vary from 30 per cent to 40 per cent of total aggregates. Sand characteristics influence water more than coarse aggregates but both should be considered together. There is little difference in amount of oversanding required with two different coarse aggregates if these

have same voids, but if two different sands are used with the same coarse aggregate the amounts required to give the same workability will vary widely. Field practice indicates need of studying grading curves on each side of division between fine and coarse aggregates or any two ranges of sizes that may be furnished for blends to insure that sizes around the division are not deficient. The sizes from ¾ in. to 10-mesh are important not only to secure strength but because they influence the mixing time. High end fraction gradings may have low voids but they need twice the mixing time of mixes with intermediate sizes. About 50 per cent of the mix should be intermediate sizes.—EDMUND SHAW

Effect of grading of gravel and sand on voids and weights. STANTON WALKER. *Nat. Sand Gravel Bul.*, Sept., 1930, V. 11, No. 9, p. 7-10.—Report of tests in Research Laboratory of National Sand and Gravel Association in 1928 on one gravel and two sands for a wide range of gradings, as preliminary studies of gravel ballast, voids in different combinations of sand and gravel and the effect of these combinations on the strength, yield and workability of concrete. Tests were on gravel separated into the following four sizes: No. 8 to No. 4, No. 4 to ⅜-in., ⅜ to ¾-in., ¾ to 1½-in., and recombined into 57 different gradings. Most of the tests were made with the three coarser sizes; the combinations were selected so that the voids and unit weights may be estimated by interpolation for any combination of the three sizes and a limited number of the four sizes. Each of the two sands was separated into three different sizes: Fine (approximately 0 to No. 48), medium (approximately No. 48 to No. 14) and coarse (approximately No. 14 to No. 4), and were recombined into 51 different gradings, arranged in such a manner that voids and unit weights may be estimated for any other combination of them. Weights per cu. ft. were determined in cylindrical measures with height approximately equal to diameter. A measure of ½ cu. ft. capacity was used for gravel tests and of ⅕ cu. ft. for sand tests. Tests were made for two methods of filling the measure—"dry and loose" and "dry and rodded." Each value is the average of two or three tests made on each grading. While report does not pretend to discuss *effect* of voids on suitability of sand and gravel for various purposes, it does contain valuable and comprehensive information on the relationship between grading of sand and gravel and its void content. Following observations from the tests are given as a guide in studies of the data: (1) For three sizes of sand or gravel, such as used in these tests, least voids were obtained for a combination of fine and coarse sizes, with intermediate size omitted. In general about 30 to 40 per cent of finer size gave least voids. (2) Combinations of two adjacent sizes, that is, fine and medium or medium and coarse showed relatively small changes in void content for different proportions. However, as in the case of fine and coarse, a combination of adjacent sizes containing about 30 to 40 per cent of the finer size had a lower void content than other combinations of two adjacent sizes. (3) General observation may be made that, for sizes used in these tests, void content of any size was reduced by addition of a finer size up to about 40 per cent or of a coarser size up to about 60 per cent. (4) There was an approximately constant difference between the voids as determined by the loose or rodded method. In case of gravel this difference was 3 to 4 per cent and in case of sand it was 5 to 7 per cent.—P. MCKIM

Effect of grading of sand and coarse aggregate on voids and weight of mixed aggregate. STANTON WALKER. *Nat. Sand Gravel Bul.*, Oct., 1930, V. 11, No. 10, p. 1-10.—These data are from hitherto unpublished tests of the Structural Materials Research Laboratory, Lewis Institute, Chicago, released for this purpose by F. R. McMillan, Director of Research of the Portland Cement Association. Complete significance of the test results cannot be considered without taking into account effect of voids on whatever finished product utilizes the mixtures of fine and coarse material. Following indications

of relationships between grading and voids seem clear from the data and should be of interest: (1) For quantities of sand greater than required to produce minimum voids the mixtures containing coarser sand produced lower void contents. (2) Coarser sands used in this investigation had lower void contents than finer ones. (3) For gravel as coarse aggregate same percentage of sand produced minimum voids, regardless of grading of sand; the minimum voids obtained with a given grading of gravel was same for different gradings of sand. (4) For granite as coarse aggregate, percentage of sand required to produce minimum voids varied as grading of sand varied; there is, however, no indication of a definite relationship. (5) Percentage of minimum voids for each combination varied with the grading of the coarse aggregate. The larger sized coarse aggregates gave the lower void contents for mixtures of sand and coarse aggregate. This relationship seems to be a function of size of particle and, probably, of size of void spaces rather than percentage of voids in coarse aggregate.—P. McKIM

Effect of moisture content on voids in sand. C. E. PROUDLEY. *Nat. Sand Gravel Bul.*, Oct., 1930, V. 11, No. 10, p. 10-12.—Free moisture in fine aggregate causes a phenomenon known as bulking, which has been the cause of considerable difficulty in undersanded mixes and over-run in cement when volumetric proportions did not take it into account. Weight proportioning has overcome much of difficulty, but where volume batching is used it is of great importance that bulking characteristics of sand be known. From study of several investigations carried out by the Structural Materials Research Laboratory of Lewis Institute, the Kansas State Highway Laboratory, and the Bureau of Public Roads, the following conclusions have been drawn: (1) Sands increase in bulk when moist. Amount of bulking depends upon percentage of moisture and method of measurement. Bulking is accompanied by increase in percentage of voids. (2) Maximum bulking is obtained with 3 to 10 per cent moisture, depending on grading of sand. Finer sands require more moisture to produce maximum bulking than do coarse sands. (3) Fine sands bulk more than coarse sands. For the usual conditions (3 to 6 per cent moisture) 20 to 45 per cent bulking may be expected depending on grading of sand and method of measurement. (4) Bulking is not a factor in measurement of sand by weight. Weight measurements, however, should take into account weight of water present at time of weighing. (5) Inundation minimizes the bulking of moist sand and gives a value approximately equal to that of the sand measured in a dry and loose condition.—P. McKIM

Proposed German standard specifications for light cast stones made from pumice. (See SHOP MANUFACTURE.)

New forming methods for small concrete buildings. (See FIELD CONSTRUCTION—Buildings.)

CEMENT

Calculation of raw mixture. A. B. HELBIG. *Zement* (Germany), Sept. 25, 1930, V. 19, No. 39, p. 919-20.—A method is given for calculating necessary amount of raw mixture to produce a certain amount of cement. Calculations are based on wet and dry processes.—A. E. BEITLICH

Tricalcium silicate. A. GUTTMANN AND F. GILLE. *Zement* (Germany), Sept. 25, 1930, V. 19, No. 39, p. 914-5.—Methods of Hansen and W. Dyckerhoff for preparation of tricalcium silicate are described; and explanation is given for the fact that R. Brill was unable to detect characteristic lines of this compound in his X-ray examinations. (cf. R. Brill, *Zement* (Germany), Aug. 21, 1930, V. 19, No. 34, p. 796 and Jaenicke, *Zement* (Germany), Nov. 21 and 28, 1929, V. 18, No. 47-48, p. 1345-7, 1388-9.)—A. E. BEITLICH

Influence of the monocalcium phosphate on the hydration of cement. KATSUZO KOYANAGI. *Kogyo Kwagaku Zasshi* (*J. Soc. of Chem. Ind.* (Japan), July, 1930, V. 33, Supplemental binding, No. 7, p. 276-7.—It was found by microscopic and physico-chemical methods that very small quantities of monocalcium phosphate retard setting of cement without considerably influencing hardening process. This phosphate has tendency to form insoluble di- or triphosphates with calcium hydroxide, which is liberated by hydration process. Hydration of calcium aluminate seems to be especially effected by above mentioned phosphate.—A. E. BEITLICH

Temperature in the mill and setting time of cements. KATSUZO KOYANAGI. *Zement* (Germany), Oct. 16, 1930, V. 19, No. 42, p. 988-9.—Reply to article written by Heiser (cf. *Zement* (Germany), July 17, 1930, V. 19, No. 29, p. 679-80.) Author describes a number of grinding tests carried out in regular cement mill and in laboratory mill. In general, cements ground in laboratory mill show slower setting properties. Second investigation deals with influence of gypsum on setting time. It was found, that gypsum loses some of its retarding properties, when its percentage in clinker exceeds a certain limit, which depends on chemical composition of clinker. Cements with high SO_3 contents become quick setting when exposed to high temperatures in mill, while cements with low SO_3 contents remain normal.—A. E. BEITLICH

Free lime in portland cement and soundness. GUSTAV HAEGERMANN. *Zement* (Germany), Oct. 16, 1930, V. 19, No. 42, p. 982-4.—Twelve different technical raw mixtures were burned in experimental furnace under same conditions at temperatures ranging from 2237° to 2687° F. Obtained materials were carefully ground (to prevent action of carbon dioxide and water of air) and tested for uncombined lime with method by Emley and for soundness with steam and cold water test. It was found that under mill conditions a good clinker can be produced at 2327° F. Based on steam tests, range of burning temperature is within 392°; based on cold water tests it is within 212° F. Steam test can give good results with clinker with up to 2 per cent uncombined lime (generally only 1 per cent), and clinker with up to 4 per cent can stand cold water test.—A. E. BEITLICH

Estimation of lime in cement. *Engineering* (England), Sept. 5, 1930, V. 130, No. 3373, p. 314.—British Department of Scientific and Industrial Research has issued Building Research, Tech. Paper No. 9, The Estimation of Free Calcium Hydroxide in Set Cement: A Calorimetric Method. The method depends upon the fact that, within small and ascertained limits, the dissociation of calcium hydroxide begins at about 350° C. and is nearly complete after ignition at 550° C. for half an hour. If therefore two parts of a sample of material containing calcium hydroxide are first heated to these temperatures for half an hour and the resulting products are then hydrated, the difference between the two heats of hydration will be a measure of the calcium hydroxide present in the sample providing no other change has been produced in the process. The aggregate error in applying the method to portland cement should not exceed .5 per cent by weight of the sample in the value of the free lime obtained.—G. M. WILLIAMS

What causes the disturbing influence of portland cement on high alumina cement? KOGAKUSCHI AND KATSUZO KOYANAGI. *Zement* (Germany), Sept. 11, 1930, V. 19, No. 37, p. 866-9.—When portland cement is mixed with high alumina cement, setting process of the latter is greatly accelerated. This fact was investigated by chemical methods and under the microscope. Setting time is lowered very much for mixtures up to 70 per cent portland cement; mixtures with more than 70 per cent portland cement approach normal setting properties. Degree of burning of clinker influences set; clinker with high free lime content causes quick setting. Great acceleration

takes place when high alumina cement is mixed with lime solutions, even 0.5 per cent CaO in solution has great effect. Reactions of high alumina cement with water and with lime water were examined under microscope. Cement reacts with water very slowly first, but more vigorously after several hours. With lime water, reaction starts almost instantaneously and becomes slower afterwards. Authors come to conclusion that hydration of monocalcium aluminate with water is reversible and slowly, while reaction between monocalcium aluminate, calcium hydroxide and water is irreversible and takes place very rapidly, which fact causes quick setting of mixtures of high alumina cement with other calcareous hydraulic materials.—A. E. BEITLICH

The degree of separation by air separators. H. MADEL. *Zement* (Germany), Oct. 9, 1930, V. 19, No. 41, p. 958-63.—Directions for valuation of air separators, which were given by P. Rosin and E. Rammler in previous article (cf. *Zement* (Germany), 1929, V. 18, No. 26-32), are discussed. Three conditions must be fulfilled by efficient air separator: (1) separator must produce a material, which has most suitable composition for any desired purpose, (2) separator must concentrate fine flour, which is present in raw material, in final product, and (3) separator must prevent undesirable oversize particles from reaching final product. Efficiency is 100 per cent only when all three conditions are completely fulfilled. A number of equations are given for a mathematical expression of above facts which enable calculation of efficiency. Same conditions are shown also in graphs. Reply by Rosin and Rammler is given.—A. E. BEITLICH

Effect of gypsum on the decomposition of tri-calcium silicate by heat. THOMAS F. MULLAN *Rock Products*, Aug. 30, 1930, V. 33, No. 18, p. 62.—Work of Myers is quoted which shows that calcium tri-silicate is decomposed by temperatures lower than that of the cement kiln. In addition it was found the decomposition to be accelerated by presence of gypsum. Experiments were made with three clinkers heated with amounts of gypsum varying from 2 per cent to 12 per cent. Free lime was determined after heating by method of Lerch and Bogue. Long heating with gypsum gave almost the free lime required by decomposition of tri-calcium silicate to di-calcium silicate and free lime. In some cases there was a slight unexplained excess of free lime. Tests of heating gypsum to 1000° C. indicated that none of the free lime was contributed by the gypsum.—EDMUND SHAW

Thielekiln. A. B. HELBIG. *Zement* (Germany), Aug. 7, 1930, V. 19, No. 32, p. 745-9.—In new type of high efficiency shaft kiln described, raw mix and powdered coal are stored in two bins under which two automatic scales are installed. Electric control device operates both scales and dumps material at same time. Screw and elevator deliver mixture to second screw in which materials are mixed and wetted with water. Wet material is pressed through steel plate with many holes about ½ in. in diameter by means of heavy steel rolls. After passing plate, material breaks up in small cylinders and is distributed over whole opening of kiln. Gases which pass upper layer have temperature of 140° to 180° C. They contain 32 per cent carbon dioxide and below 1 per cent carbon monoxide and oxygen. About 12 to 16 in. below surface begins sintering zone of clinker. Carbon dioxide of raw mixture forms with carbon of fuels carbon monoxide, which combines with oxygen of air for combustion to carbon dioxide. Combustion air is preheated. Total height of kiln is 25 ft., and its output is 120 to 140 tons of clinker per day.—A. E. BEITLICH

The Italian cement, lime and gypsum industries. R. DECKERT. *Tonind. Ztg.* (Germany), 1930, V. 54, No. 76, p. 1229-30. The Italian manufacturers of cement, lime and gypsum are in a single association. They make alumina, high strength portland, standard portland and natural cements, the

last class making up about 55 per cent of total. There are 140 cement mills with 800 kilns and 20,000 employees. Firms making cement products number 2,440 with 21,746 employees. Lime, mostly hydraulic, is burned in 586 plants with 1000 kilns and 6,000 workers. Gypsum is burned in 115 plants by about 1000 workers. Annual production in millions of barrels (200 kg.) is about: natural cement 22, portland cement 17, lime 12.5 and gypsum 4.—F. O. ANDEREGG

Stirring and mixing of slurry. A. VOGT. *Zement* (Germany), Aug. 21, 1930, V. 19, No. 34, p. 809-10.—Equipment consists of cylindrical reinforced concrete tank, about 20 ft. wide and 33 ft. high, with conical bottom for mixing slurry in wet cement plants. Its capacity is about 6,700 cu. ft. Compressed air of 2 atm. pressure, which enters tank at bottom is distributed and stirs slurry. A second cylinder, open at top and bottom, diameter of which is about half of that of tank, with openings in its sides, is held in vertical position in center of tank. Upper edge of cylinder must always be below surface of slurry. Slurry is forced upwards through inner cylinder, flows over its top and through side openings and moves downwards between walls of cylinders. When it becomes necessary to add dry raw material to slurry, a cylindrical sieve will be installed between both cylinders. Material circulates 20 times per hour. Calculations show speed of slurry and power consumption.—A. E. BEITLICH

Use of powdered coal and crude oil in the rotary cement kiln. AFTON J. BLANK. *Rock Products*, Aug. 30, 1930, V. 33, No. 18, p. 53.—Records are given from kilns using powdered coal and crude oil as fuel. Heat used varies from 1,212,840 B. t. u. to 1,745,264 B. t. u. Both kilns used crude oil, but with one exception the powdered coal fired kilns gave higher clinker outputs. Author concludes that wide differences in heat consumption are partly due to composition of cement but are mainly due to differences in kiln operators. Not only fuel economy but the life of the kiln lining depends upon the skill of the burner. Instances are cited where unskilled men have burned out expensive linings of high alumina brick in a short time.—EDMUND SHAW

Studies on calcium ferrites and iron cements II. SHOICHIRO NAGAI AND KATSUHIKO ASAOKA. *Kogyo Kwagaku Zasshi* (*J. Soc. of Chem. Ind.* (Japan), May, 1930, V. 33, Supplemental binding, No. 5, p. 161-4.—Pure dicalcium ferrite was prepared by extraction of free lime from product obtained by heating of mixtures of $3CaO:1Fe_2O_3$ and $5CaO:1Fe_2O_3$ at 1350° C. and 1550° C. It is stated that dicalcium ferrite is ferrite with highest lime content. Monocalcium ferrite $CaO.Fe_2O_3$ was prepared by heating a mixture of 1 CaO and 1 Fe_2O_3. Combination begins at 1000° C., proceeds very slowly up to 1150° C. and ends at 1200° C. when entire mass melts. Solubility of monocalcium ferrite in hydrochloric acids of different concentrations (0.5 to 3.0 normal) was determined. Method was derived to separate dicalcium ferrite and monocalcium ferrite from their mixtures. Method is based on the different solubilities of these compounds in hydrochloric acid.—A. E. BEITLICH

Comparison of balls and cylpebs as grinding media. K. KOYANAGI. *Rock Products*, Aug. 16, 1930, V. 33, No. 17, p. 58.—Although grinding capacity of balls is larger than that of cylpebs it is rapidly reduced by cement that sticks to the balls. On this account the balls show the worse result in grinding. Cylpebs probably grind less by impact and more by friction than balls so adhering cement is rubbed off. The author found more "flake" cement in ball than in cylpeb product which tended to confirm this theory. Opening a 14-ft. ball mill that had been stopped suddenly showed a rapid increase in fines up to 6 ft. after which the curve tended to flatten out. With cylpebs the relation between fineness and length was more regular, the curve being nearer to a straight line.—EDMUND SHAW

Tube mill grinding. A. B. HELBIG. *Zement* (Germany), Sept. 11, 1930, V. 19, No. 37, p. 870-3.—Author describes different degrees of fineness to which materials in cement industry must be ground. Raw materials must be so fine, that sintering in kiln takes place at lowest possible temperature. Raw mixture and burned material will gain in uniformity with increasing fineness. All particles should have approximately same size so that they reach necessary temperature in kiln at same time. Coal for shaft kilns should be ground finer than it is now in practice in order to accelerate sintering process. For rotary kilns, coal should be uniform in particle size. Its fineness depends on percentage of volatile material. Cement should be ground very fine to uniform sizes without making operation uneconomic. Tests were made to study grinding process in compartment mills and suggestions are given for economic dimensions and practical installations of air separators. (cf. Grosse, Foerderreuther and Rammler, *Zement* (Germany), Feb. 27 and March 6, 1930, V. 19, No. 9-10, p. 189-94, 214-7; *J. Am. Concrete Inst.*, May, 1930, V. 1, No. 7, Abstr. Sect. p. 92; Naske, *Tonindustrie Zeitung* (Germany), March 20, 1930, V. 54, No. 23, p. 386.)—A. E. BEITLICH

Researches on the rotary kiln in cement manufacturing. Part II. GEOFFRY MARTIN. *Rock Products*, Aug. 16, 1930, V. 33, No. 17, p. 60.—This part discusses methods of calculating the fuel consumed in a rotary kiln by analysis of coal, exit gases, raw mix and clinker. Three methods are given. The first is the author's own, based on the fact that fuel consumption is a function of volume of CO_2 per 100 volumes of air-free nitrogen in exit gases. Instructions are given for making a table or curve from which coal consumption may be read after CO_2 volume of exit gases has been found. Second method is a calculation made from volume percentage of nitrogen in exit gases. Third is by the Kuhl's formula which the author has found to give low results but which he thinks would give correct results with calibration of instruments and calculated constants.—EDMUND SHAW

Researches on the rotary kiln in cement manufacture. Part III. GEOFFRY MARTIN. *Rock Products*, Sept. 13, 1930, V. 33, No. 19, p. 57. This reviews the author's work for the British Portland Cement Association on heat losses due to formation of carbon monoxide and admission of excess air. Statistics from 2139 analyses of exit gases show best result is obtained with present conditions when exit gases show 1.1 per cent free oxygen. But in practice this figure is never maintained, the actual content fluctuating from 0 per cent to 7 per cent. Author says this indicates that burners are vigilant in watching burning and constantly correcting air supply, but that the eye is not a sufficient guide. He proposes and explains the use of an indicator by which oxygen in the exit gases may be kept between 1 per cent and 2 per cent to save from 50 to 150 tons of coal a week in operation of a 200-ft. kiln, according to the degree of prevailing mismanagement. In many cases increases of 10 per cent to 40 per cent output may be obtained. A number of tables and charts are presented, with formulas needed for kiln testing and their derivation.—EDMUND SHAW

A development in air classification. GEORGE ADAMS ROLFE. *Rock Products*, Aug. 2, 1930, V. 33, No. 16, p. 47.—The air classifier described is a tower through which the material falls against an ascending current of air. Outlets with catch basins allow part of the air to escape at different heights carrying a sized product with it. The velocity of the air is greatest at the bottom and least at the top. Experiments have been made on a unit handling from three to five tons per hour. Although originally designed for separating mica, the classifier may be applied to the grinding of cement and is particularly adapted to slag grinding. The author points out that the device has no moving parts and there is nothing in it that can wear out.—EDMUND SHAW

Decrease of water content of slurry in manufacture of portland cement by wet process. PETER P. BUDNIKOFF, G. W. KUKOLEW AND W. M. LESCHOJEW. *Kolloid Z.* (Germany), Sept., 1930, V. 52, No. 3, p. 341-8.—Advantages and economy of wet process are characterized. New method is described, which enables reduction of water content of slurry without decreasing fluidity. Investigations were based on normal mixtures of limestone and marl with 48 per cent water. Heat calculations and viscosity determinations of this mixture were made. Additions of certain bases, like Na_2CO_3, Na_2SiO_3 or NaOH in concentrations from 0.005 to 0.15 normal, increase viscosity. Peptonization is caused by OH-ions. Sodium silicate shows greatest effect, while sodium hydroxide absolutely destroys fluid properties. Additional studies were made with molasses solutions. A theory is derived explaining coagulation and peptonization. Decrease of water offers many advantages, less heat is consumed, grinding process is accelerated, hardness of water is reduced by additions and dimensions of equipment can be reduced. (cf. *Zement* (Germany), Jan., 1930, V. 19, No. 5, p. 96.)—A. E. BEITLICH

New device for the removal of rings in rotary kilns. *Zement* (Germany), Oct. 9, 1930, V. 19, No. 41, p. 963-4.—A new type of cement gun is described. Special features of apparatus are great mobility, ease in aiming at any desired point and low expenses. Bullet weighs about 4 ounces.—A. E. BEITLICH

Researches on the rotary kiln in cement manufacture. GEOFFREY MARTIN. *Rock Products*, Aug. 2, 1930, V. 33, No. 16, p. 49—This is the first of a series of 27 articles. The author says that a complete theory of the rotary kiln has been worked out. Efficiency is barely 19 per cent showing a wide scope for improvement in design and operation. With a slurry containing 40 per cent water, fuel consumption should be about 21 tons standard coal for 100 (long) tons clinker produced. Of supreme importance in fuel economy is maintenance of as high a flame temperature as possible in combustion zone. Only B. T. U.'s above 805 C. can be directly utilized for forming clinker and merely preheat the slurry. Losses of heat by radiation and convention, both inside and outside the kiln are far more important than they were thought to be.—EDMUND SHAW

Some errors in rapid methods of mix control. S. L. MEYERS. *Rock Products*, Aug. 2, 1930, V. 33, No. 16, p. 60.—Reasons why the acid-alkali titration, ignition loss and lime soluble in HCl from raw or calcined raw mix are not absolute criterions of what will be the lime in burned clinker, are acid-insoluble compounds in the raw mix and variations in composition of the dust carried up the stacks of kilns by the waste heat gases. A long list of acid-insoluble lime minerals is given, the commonest those of the pyroxene group, such as augite and hornblend, and some of the feldspars and garnets. There are also lime minerals only partly soluble in acid. Dust losses vary with materials in raw mix. With high and low limestones the high grade limestone powders readily after calcination and much goes out with the stack dust, thus lowering the lime in the clinker. The effect is apt to be reversed where clay is used as the low, as the clay is more easily picked up by the exit gases.—EDMUND SHAW

Influence of use of high quality aggregates on quality and costs of concrete. "Einfluss der Verwendung von Edelzuschlag auf die Guete und die Kosten von Beton." PAUL HERTEL. 1930, Charlottenburg 2 (Germany), R. M. 2.00. Reviewed in *Zement* (Germany), Sept. 18, 1930, V. 19, No. 38, p. 906.—Results of comprehensive investigation are published concerning effect of aggregate gradation on consistency, weight, strength and water permeability of concrete. Costs of aggregates and concretes are compared. Tables and graphs explain this investigation.—A. E. BEITLICH

Rapid determination of magnesia in portland cement and raw materials. AUTHUR J. POOL. *Rock Products*, Aug. 16, 1930, V. 33, No. 17, p. 80.—The method of determining magnesia by weighing as $Mg_2 P_2 O_7$ is accurate but tedious. The author prefers a volumetric method. The sample is dissolved in dilute hydrochloric and nitric acids and iron and alumina are precipitated with ammonium hydroxide. Lime is precipitated as calcium oxalate and determined by potassium permanganate titration. Magnesia is determined on the filtrate from lime by precipitation with known volume of sodium hydroxide and titrating the filtrate with hydrochloric acid for excess. Article notes several details which must be carefully attended to for a correct result. It is especially important that all the ammonia be expelled before titrating. Magnesia is calculated from the amount of sodium hydroxide required to precipitate it.—EDMUND SHAW

Small-piece testing method for strength of cement mortars IV. S. NAGAI. *Kogyo Kwagaku Zassi* (*J. Soc. of Chem. Ind.*) (Japan), March, 1930, V. 33, Supplemental binding, No. 3, p. 290-5.—New method was derived and investigated by author to test strength of cement mortars with test pieces, which are much smaller than normal sizes. Tests were made with portland cement, blast furnace slag cement and several high alumina cements and one Soliditit cement comparing obtained results with normal testing methods. It was found, that in general lower results were obtained after 28 days combination storage than after 28 days water storage, when tested by small-piece testing method. No increase in strength of high alumina cements was observed after long water storage. Author claims, that this fact is due to solution of a tricalcium aluminate which is formed during hydration of $5CaO.3Al_2O_3$ and monocalcium aluminate.—A. E. BEITLICH

Are you getting the true lime value on your raw mix analysis? ROBERT R. KING. *Rock Products*, Aug. 2, 1930, V. 33, No. 16, p. 60.—Where lime is determined by either gravametric or volumetric methods after fusion with alkaline carbonates an error as much as 2 per cent to 3 per cent may be introduced. Tables show that fusion with varying amounts of $Na_2 CO_3$ from 0.2 gram to 8.09 gave from 75.48 per cent to 80.33 per cent apparent $Ca CO_3$ content. This is because sodium and potassium salts formed in fusion cannot be washed out in spite of their high solubility. Remedy suggested is to use as little alkaline salt for fusion as possible. The author states that with 20 per cent insoluble in the 0.5 grams sample of raw mix only 0.1 grams of fusion mixture is necessary.—EDMUND SHAW

Raw grinding and slurry control. R. J. BINFORD. *Rock Products*, Aug. 2, 1930, V. 33, No. 16, p. 41.—Maximum production in a grinding plant is only accomplished by having proper size of grinding media in each mill compartment. The author gives the formula for the proper size of largest ball. Largest practical size is 5-in. dia. as with larger balls repairs on tube mill are heavy. The feed should therefore all pass a 1½-in. screen and nearly all should pass a 1-in. screen. Control of slurry covers: Grinding to the required fineness for burning and for desired quality, maintaining as low moisture content as will allow the slurry to be handled easily and quickly and maintaining a correct chemical balance of different compounds necessary in finished cement. The finer the grinding the better the results in the kiln but as fine grinding is expensive materials are ground to point where maximum demand for quality is satisfied. For economy's sake water in slurry is kept as low as is consistent with quality. At the West Penn. plant, where the author has charge of mechanical departments, economical point is 33 per cent to 35 per cent moisture.—EDMUND SHAW

Standardizing cement sieves. E. TAYLOR. *Rock Products*, June 21, 1930, V. 33, No. 13, p. 85.—The author gives his method, used by the Cebu Portland

Cement Co., Naga, Cebu, P. I., for correcting the fineness sieve test. A 200-mesh sieve is checked and calibrated by the U. S. Bureau of Standards. A large bottle of cement, fineness of which has been determined by this sieve, is kept in laboratory and each tester is required to test a sample of this cement with sieves actually used in testing the shift's run. Results are entered on a card without correction. Results are averaged by laboratory chief and compared with true fineness of the bottle cement and the necessary corrections determined for sieves in use. These corrections are applied until new corrections are ordered. System insures correct results and has the advantage that checked and standardized sieve is used only occasionally.—EDMUND SHAW

Internationalization of standards. V. M. ANZLOVAR. *Zement* (Germany), Oct. 2, 1930, V. 19, No. 40, p. 942-3.—Standard specifications for cements were revised in several countries. Holland and Italy were first to work out specifications for high alumina cements, Spain followed their example. High alumina cements must contain more than 40 per cent Al_2O_3 and less than 12 per cent Fe_2O_3; fineness must be: not more than 0.5 per cent residue on 75 mesh sieve and not more than 6 per cent residue on 175 mesh sieve; time of initial set shall not be less than 30 minutes and final set shall not be later than 4 hours. Tensile strength is tested with neat cement briquets. New concrete testing method for compressive strength is introduced. Standard 7.9 in. cubes are prepared from following mixture: 659.2 lbs. cement per 35.3 cu. ft. concrete, 30 cu. ft. broken stones (0.37 to 0.59 in.), 14.1 cu. ft. sand (0.04 to 0.06 in.) and 34.3 gallons of water per 35.3 cu. ft. concrete. Compressive strength after 1 day must be at least 3150 lb. per sq. in. and after 28 days 3270 lb. per sq. in. Similar specifications are given for high early strength cements. (cf. Platzmann, *Zement* (Germany), Jan. 2 and 16, 1930, V. 19, No. 1 and 3, p. 4-7, 49-52; *Ibid*, July 24, 1930, V. 19, No. 30, p. 701-2; *J. of the Amer. Concr. Inst.*, March, 1930, V. 1, No. 5, Abstr. Sect. p. 48; *Ibid*, Oct., 1930, V. 2, No. 2, Abstr. Sect. p. 23.)—A. E. BEITLICH

German standard specifications for portland cement, iron portland cement and blast furnace cement. *Zement* (Germany), Sept. 18 and 25, 1930, V. 19, No. 38-39, p. 890-9, 915-9.—New proposed standard specifications, open for objections until Nov. 1, 1930, differ from old specifications in following points: Specifications for high testing cements are added, limits for compressive and tensile strength are raised considerably, definition for blast furnace slag cement was changed. Specifications are divided into three parts. Part 1. Definition and properties. (1) Portland cement: loss on ignition should be less than 5 per cent, MgO less than 5 per cent and SO_3 less than 2.5 per cent (ignited base). Ratio between CaO and sum of soluble SiO_2, Al_2O_3, Fe_2O_3 and MnO should not be smaller than 1.7. Additions of foreign materials after burning process must be below 3 per cent. Not more than 35 per cent of raw materials, dried at 212° F., should be retained on 175 mesh sieve. (2) Iron portland cement: must contain at least 70 per cent portland cement and not more than 30 per cent granulated basic blast furnace slag. Ratio between 1 CaO + 1 MgO + $\frac{1}{3}$ Al_2O_3 and SiO_2 + $\frac{2}{3}$ Al_2O_3 in slag should be greater than 1. (3) Blast furnace slag cement: this cement is ground mixture of granulated blast furnace slag (having same ratio as for iron portland cement) and 15 to 69 per cent portland cement. Slag should not contain more than 5 per cent MnO. CaO content is in general below 55 per cent. Fineness for all three cements must be 2 per cent retained on 75 mesh sieve and not more than 25 per cent retained on 175 mesh sieve. Hardening should not start sooner than 1 hour after mixing cement and water. Following strength data must be reached of 1:3, cement: standard sand, mixture:

	Cement		High Testing Cement	
	Compr.	Tens.	Compr.	Tens. Str.
After 3 days water storage	....	...	3555	355.5
After 7 days water storage	2560	256	....	....
After 28 days water storage	3910	...	....	....
After 28 days combination storage	4977	427	7110	569

Water storage means: 24 hours in moist closet then in water (63 to 68° F.). Combination storage means: 24 hours in moist closet, then 6 days in water and then 21 days in air (63 to 68° F.). Part 2 discusses sampling, preliminary tests, preparation of materials for standard tests, determination of fineness, initial and final set and soundness, also mixing, making, storage and breaking of cubes and briquets. Specimens for compressive strength tests are 2¾-in. cubes and for tensile strength are briquets with smallest cross section of 0.77 sq. in. Part 3 deals with standard sand, its chemical composition and grain sizes. Standard specifications for sieves are given. Apparatus for determining setting time, for mixing mortars, hammer apparatus and tensile strength tester are described. Exact dimensions of test pieces and their molds are given and also allowable tolerances for manufacture and wear.—A. E. BEITLICH

California's largest cement mill keeps up-to-date *Rock Products*, June 21, 1930, V. 33, No. 13, p. 41.—Oil fuel for the Santa Cruz Portland Cement Co.'s plant at Davenport, Calif., is pumped from tankers to storage tanks on shore about three miles from the plant. The line rests on the ocean bottom for one-half mile. This is one of the few places where oil is pumped from open sea to plant storage. Limestone is mined from glory holes above bulldozing chambers connected by chutes to two main haulage tunnels. Clay overburden supplies most of clay needed for the mix. Mining is safer than quarrying. Costs of opening one glory hole with bulldozing chamber and tunnels was $26,000, about 86¢ per ton for development. Blending begins by keeping coarse and fine limestone separate and combining as needed. The fines carry much clay. A second blend is made by drawing proportionately from "hi-low" bins containing crushed product. This blend goes to 40 steel hoppers and a mix from these goes to Hardinge raw grind mills with air separators, either Hardinge or Sturtevant. A heavy circulating load is carried. Grinding is 90 per cent minus 200-mesh. Hardinge mills finish grind clinker after it has been crushed in rolls in closed circuit with vibrating screens. Gypsum is calcined in Raymond "calcine-while-you-grind" mills. Six ball and six tube mills grind "oil well" cement which is ground finer and harder burned and approaches high early strength cement in its properties.—EDMUND SHAW

Modern cement testing laboratory. *Rock Products*, June 7, 1930, V. 33, No. 12, p. 75.—The new laboratory of the Southwestern Portland Cement Co., at El Paso, Texas, has been successfully designed to eliminate unnecessary noise. All grinding machines have texrope drives and are mounted on lead cushions. The rotap screening machine is placed in a cabinet lined with celotex and mounted on a lead cushion. The moist room is kept within 1° F. of 70°. It has double concrete walls insulated with tarred cork-board. There is one large door for entrance and two small doors for attending to specimens while they are setting up. A 5-h. p. Kelvinator and four Chromolox strip heaters control the temperature. They are regulated by two thermostatic mercoid switches. Sprays keep the air at almost 100 per cent humidity. A wet and dry bulb recording thermometer keeps a continuous record of temperature and relative humidity. Average range of temperature for 24 hours for practically all records is within 0.2°. Physical testing bench tops are of ¼-in. non-rusting steel plate. The bench for titrations has a glass plate with an electric light below.—EDMUND SHAW

Plant of Republic Portland Cement Co. in second year of production. *Pit Quarry*, Aug. 13, 1930, V. 20, No. 10, p. 17-34.—Wet-process plant with rated capacity of 3,600 bbl. per day has actually produced as high as 3,900 bbl. Raw material is quarried from argillaceous limestone or chalk which varies from soft earthy to fully solidified rock. A large bed of natural cement rock constitutes about 80 per cent of deposit. Broken stone from quarry is loaded by electric shovel into 8-cu. yd., side-dump, standard-gauge steel cars and hauled to plant by gasoline locomotive. Crusher will take feed as large as

2-cu. yd. and reduce it to ¾-in. in a single operation. One building houses the raw and finish grinding mills and the power equipment. The two types of limestone are fed, from the bins to two compeb mills. Slurry is ground to a fineness of 90 to 95 per cent through a 200-mesh sieve and is discharged into a horizontal sump and stirred by a double-ribbon conveyor. With a water content of 42 per cent it is handled by two 6-in. pumps, through a 10-in. line in a tunnel underneath the storage, to slurry tanks on opposite side. Same tunnel is used by pedestrians and for air, water, and electric lines. The six blending tanks with four correction tanks hold slurry for 48-hour run. Each tank has a mechanical and air agitator driven by motors through speed reducers. The chemist samples slurry in each blending tank while filling, and corrections are made by transfers. Two kilns are fired with natural gas at 1½ lb. pressure, and equipped with temperature recorders. Slurry enters the kilns through ferris-wheel feeders. Feed end of each kiln is within a dust chamber which connects by steel breeching with its 200-ft. reinforced-concrete stack. Clinker from kilns passes to coolers which discharge to the clinker storage pit. The clinker is taken by crane to finish-mill feed bins. Table feeders pass clinker and gypsum to compeb mills. A dust-collecting system on a mezzanine floor serves also as a ventilator. Pneumatic pumps in basement propel finished cement to tops of storage silos having total capacity of 153,000 bbl. Packhouse is a 4-story building adjacent to the cement storage. Cross screw extends outside to a loading track for loading bulk shipments through a 6-in. rubber hose. An air-jet in the hose keeps the line clear.—A. J. HOSKIN

Reactions during setting and hardening process of cement. (See PROPERTIES OF CONCRETE.)

Temperature and cement. (See PROPERTIES OF CONCRETE.)

PROPERTIES OF CONCRETE

Reactions during setting and hardening process of cement. TUTOMU MAEDA. *Zement* (Germany), Sept. 4, 1930, V. 19, No. 36, p. 842-3.—A theory is derived illustrating reactions which take place during setting and hardening periods and explaining hardening properties of cement. Certain constituents of cement form when mixed with water unstable compounds in a system containing one liquid phase. Second step is formation of oversaturated solution of stable compound. When a new solid phase precipitates from this oversaturated solution, it absorbs certain constituents of the liquid phase, which form a film around particles. Conditions for a proper hardening are: (1) particles, which separate from liquid phase, must be small, which gives great surface, (2) particles must be separated by adsorbed film, thickness of which lies in molecular range. No liquid phase should be present. (3) Attractions between the different particles and particles and film must be great, and (4) particles must have great strength. A number of experiments with ultra-microscope, which seem to prove existence of colloidal parts, are described. (cf. *Supplement to Scientific Papers of Inst. of Phys. and Chem. Research* (Japan) Tokyo 1928, V. 8.)—A. E. BEITLICH

Temperature and cement. OSCAR FABER. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930. Abstracted from *Concrete Constr. Eng.* (England), Oct., 1930, V. 25, No. 10, p. 566-569.—Curves are given showing relation between temperature and time of setting for different kinds of cement. A case is cited where a recorded rise in temperature of 50 degrees occurred in three days after placing of the cement. Use of this property of heat production can be made by insulating concrete thus preventing concrete from cooling too rapidly until it is hard. Reference is made to

Bulletin No. 81, Engineering Experiment Station, University of Illinois, to point out the increase in the strength of concrete with increase in the temperature at which it is cured.—JOSEPH MARIN

Chemical characteristics of cement pipe lining. E. L. CHAPPELL. *Ind. Eng. Chem.*, Nov., 1930, V. 22, No. 11, p. 1203-6.—A brief review of literature regarding use of cement pipe lining and theories advanced to explain its effectiveness as a protective layer are given. Data are presented showing change in chemical composition that took place in several types of cement during exposure. The ages of the linings examined varied from one to two years with hot water exposure and from five to 60 years with cold water exposure. It was found that calcium is gradually leached out and iron hydroxide deposited and that this exchange did not result in disintegration of lining nor alter the effectiveness of the coating in preventing corrosion. The deposition of iron hydroxide will take place in a layer of sand and finally cement the sand into a hard coating. Cement pipe linings have been found to be excellent protection in tuberculating water and also good results were obtained with salt water and sulfur water. If CO_2 content in steam is high in steam return lines, it has a solvent action on both the iron and calcium compounds and destroys some cement linings.—ROY N. YOUNG

The elasticity of concrete. H. H. LANGDON. *Monthly Bull. No. 30*, Washington State College, April, 1930, V. 12, No. 5, 48 p.—Data were taken from three sources: student work, control specimens from campus construction jobs, and from field jobs. Special apparatus used to measure deformations, consists of two steel rings, each clamped to the specimen by three equally spaced screws. Connected between the rings are three equally spaced metallic bellows. The three bellows are interconnected by means of small tubes. Another small tube extends from one of the bellows to a glass tube placed at a small angle from the horizontal. Any deformation in the specimen forces a small quantity of water through the bellows and tubes into glass gage where it is easily read. A comparison was made between the results obtained with this type gage and with mirror type. Satisfactory agreement was found. A screw machine and hydraulic machine were used to produce loads. Two hundred and forty specimens were tested. Tests were conducted to prove that slight curve at lower end of stress-deformation diagram was due to a lack of accuracy in the weighing of loads, or in part due to the compressometer or to temperature changes, and is not indicative of true deformation within the concrete. The major conclusions state that: concrete is elastic in the same sense that steel is considered elastic; elastic limit occurs at approximately 37 per cent of ultimate; the relationship between elastic limit and ultimate stress is fairly constant; if elastic limit is not exceeded, concrete may be reloaded and same stress-deformation relations will be obtained; modulus of elasticity as found is considerably higher than that used in present day design; there is a relationship between ultimate strength and modulus of elasticity. There are also enumerated several conclusions that need additional verification. A resume of studies made by other experimentors in the same field is also given.—IRA L. COLLIER

Corrosion of structural steel and steel reinforcing rods encased in concrete. E. A. CROSS. *Engineering* (England), July 4, 1930, V. 130, No. 3364, p. 30.—Structural steel encased in concrete and steel rods in a reinforced concrete slab supported by the structural steel beams were noted in a 26-year old engine room of a Toronto store. The construction consisted of 18-in. steel beams, span 25 ft., spaced 3 ft. 9 in. on centers embedded in concrete which supported a 6-in. concrete slab with ½-in. diameter bars, 6 in. on centers, placed in the lower part of the slab. This floor supported an ammonia refrigeration brine tank which had been leaking for a long period. A pump room immediately below this floor contained steam mains which leaked and resulted

in condensation which kept the concrete near openings wet and at a temperature of near 100° F. Cracks were found running longitudinally with steel beams and the slab reinforcing rods. It was concluded that corrosion had been caused by the following factors: (a) Cracks in concrete slab due to omission of negative reinforcement over steel beams, (b) presence of water and brine solution on top of slab finding its way through these cracks, (c) excessive condensation at under side of slab at openings in floor combined with high temperature. In repairing, steel beams were left in position but their assistance was ignored and new concrete beams as well as new slab were poured around and above them. Mixture used was 1:2:3, giving strengths of 1500 and 1850 lb. sq. in. at 7 days. —G. M. WILLIAMS

Lightweight concretes. *Builder* (England), Sept. 12, 1930, V. 139, No. 4571, p. 436.—With modern framed structures the weight of filling walls needs be reduced to a minimum to permit use of lighter steel sections. Clinker concrete slabs are very light and fire-resistant, so long as no combustible matter is present in the clinker. Peeling of plaster from clinker concrete slab walls may be due to expansion of combustible matter in concrete. Clinker concrete should never be used to cover steel nor be reinforced, on account of its porosity and probable presence of sulphur in clinker. Slabs may be covered with plaster, or, if made with ⅜-in. crushed clinker and "fines," a smooth face may be obtained. Clinker concrete walls offer considerable resistance to penetration of moisture, notwithstanding their great permeability. Pumice concrete is another lightweight concrete, suitable for building, where its high cost is not prohibitive. While having the same advantages as clinker concrete, pumice concrete has no dangers from sulphur presence. The usual mix is six parts of pumice to one of cement, fines often being omitted, to give greater voids. Voids may be artificially produced by mixing a chemical with cement, causing it to bubble and become honeycombed with air pockets. Finely ground aluminium and zinc used in these patented processes, react with lime to form hydrogen. Considerable insulating properties against heat and sound are produced in these "cellular" concretes. Sawdust concrete is a further type of lightweight concrete, the inflammable nature of the aggregate and considerable amount of its expansion, when wet, being most serious difficulties to overcome. Addition of calcium chloride to gauging water may obviate these difficulties, producing a "half-weight" concrete. By mixing small particles of ice with cement and sand, and moving the molds containing mix to a warm room, light cellular concrete may be obtained. The ice melts and hydrates the cement which forms a thin wall round the spaces occupied by the ice. Column shuttering may be dispensed with if hollow precast blocks of lightweight concrete are placed one on the other and filled with concrete and reinforcing steel. Fire resistance is thus considerably increased.—JOHN E. ADAMS

Deterioration of structures in sea water. *Can. Eng.*, Oct. 28, 1930, V. 59, No. 18, p. 593.—Tenth interim report of Institute of Civil Engineers, Great Britain, refers to experiments on the measure of resistance of reinforced concrete to deterioration by sea air and sea water. Three hundred reinforced concrete test pieces are being prepared for exposure in artificial sea water, in a sea water tank at Sheerness Dockyard and in the sea at Takoradi on the Gold Coast. The variables include 4 different kinds of cement with trass replacing a part of the cement or part of the aggregate. Three proportions are used and the medium richness will include wet and dry consistencies. Reinforced concrete test blocks were examined at Brisbane after 11 years exposure. Tar coatings have retarded but have not prevented deterioration of embedded steel.—G. M. WILLIAMS

High-early-strength concrete. S. RORDAM. *Rock Products*, Aug. 30, 1930, V. 33, No. 18, p. 45.—High-early-strength concrete may be made by using special quick-hardening cements, or from ordinary portland cement by

control of the water-cement ratio. The author believes that latter method will give desired strength in specified time for least money and that it offers better insurance against unexpected stresses at later periods. Results of a comparative experiment made under uniform conditions are given in tables and diagrams. Water-cement ratio of portland cement concrete was controlled to give same strength as that of high-early strength concrete at three days. Considerably higher strengths at 28 days and 90 days than that of the high-early-strength concrete were obtained.—Edmund Shaw

Control of the manufacture of concrete. Luigi Santarello. *L'Industria Italiana Del Cemento* (Italy), Feb., 1930, p. 16-19.—Italian concrete industry fails to apply fully available information in regard to concrete quality control as a good deal is left to the judgment of the laborer at the mixer. Quality of concrete depends on quality of materials and how they are proportioned. Cement is accepted as of good strength. It is suggested that aggregates be subjected to petrographical analysis to detect decomposable material. Feldspar is cited as such an objectionable material not indicated by usual analysis. Combination of aggregates on basis of laws of Fuller or Bolomey is recommended to give economy and density. Water-cement ratio is stressed as the one most important factor to control. Proper apparatus is available for measuring materials for concrete, and should be used.—C. G. Clair and M. N. Clair

Exposed surfaces of concrete and their protection. A. B. MacMillan. *J. Boston Soc. C. E.*, Oct., 1930, p. 467-473.—The causes of the disintegration of exposed concrete surfaces are discussed and water is indicated as the primary factor. Water weakens concrete through solution of hydrated cement compounds, expansion or freezing and the corrosion of the steel. It gains access to the concrete mass through cracks and porosity of the concrete. The precautions necessary to delay disintegration are to use proper materials, proportions, mixings, placing and curing procedure in the original construction. In addition integral water proofing material may be applied but author favors sealing concrete surface with an elastic varnish and covering varnish by a paint. Detail specifications and procedure for repairing the surface of a reinforced concrete building are given. All rusted reinforcing steel was cleaned and painted with asphalt paint. Loose concrete was removed and replaced by 1:2 mortar mixed five hours before use. The surfaces were painted with two coats of concrete paint. The total cost was $6,048 or 12¢ per sq. ft. of gross surface area. This gives a cost of 1¢ per sq. ft. per year cost to owners for surface deterioration.—Miles N. Clair

Ready mixed concrete. Miles N. Clair. *J. Boston Soc. C. E.*, Oct., 1930, p. 474-480.—The lack of durability of concrete structures in the past is due to failure to appreciate value of definite control of the proportioning, placing and curing of the concrete. Control of concrete quality is too complex a matter to be left in hands of usual concrete foreman, and an engineer of special training is required. Small projects cannot stand expense of such control. Ready mixed concrete operations are large enough to warrant expense for control of quality. The several systems for producing ready mixed concrete and equipment used are described and their limitations discussed.—Miles N. Clair

Reinforced concrete chimney stacks. *Builder*, Oct. 17, 1930, V. 139, No. 4576, p. 664.—In reply to request for information concerning suitable aggregate for a reinforced concrete chimney stack, 150 ft. high, 7 ft. 3 in. to 9 ft. 9 in. diameter internally, with temperature of flue gases at base 750° F. and a firebrick lining to be carried up 25 ft., Building Research Station states that deterioration would be due to effect of heat on aggregate and effect of gases on concrete and cement, and stresses due to temperature gradient through the walls. Ordinary clean gravel or crushed stone should withstand the heat since

the temperature would be less than that at which calcium carbonate decomposes. Portland cement, however, would commence to dehydrate slowly and lose strength mainly on inner surface, near base. Effect of sulphur gases in fumes would only cause surface reactions, provided the concrete is dense and well compacted. Stresses due to unequal temperature and drying conditions would probably cause shrinkage cracks.—JOHN E. ADAMS

Water permeability of cement pipes. E. SUENSON. *First International Congress for Conc. Rein. Conc.*, Liege (Belgium), Sept. 1930; Publication No. VII-2, 19 pp. Editor: La Technique des Travaux, Liege.—Test pipes 3½ in. long, with 2 in. outside diameter, and walls ⅜ in. thick were made of ordinary portland cement and sand of 0.2 in. particle size in mixtures ranging from 1:2 to 1:5. Corresponding water additions were 9.2 to 8.0 per cent. Pipes remained in moist closet for 24 hours, then half of samples were stored in air saturated with water, the other half under water for 27 days. The 28 day old test pipes were then kept in air until used for tests. Volume of pipes was determined by immersion in mercury and weighing overflowing mercury. It was found that specific gravity decreases with decreasing cement content. Specific gravity is greater after air storage than after water storage. Experiments to determine water permeability were made with simple apparatus with pressures ranging up to 8 ft. water pressure, kept constant throughout tests. Theory concerning flow of water through concrete was derived. Formulas and graphs show changes of flow with increasing pressure, relation between velocity of flow and internal pressure in voids and velocity and pressure in cylindric walls. Amount of water in grams which passed walls of pipes per minute was determined under different pressures and conditions. Permeability is lowered considerably with increasing cement content. Impermeability of pipes is several hundred per cent greater when specimens are stored in water than in air storage. Storage conditions are of much greater importance than composition of mix. Lean mixtures can be made dense by storage under water. Admixtures like water-glass or soap solutions have only minor influence on water impermeability. When water is slightly acid cement will be dissolved, while ordinary water and distilled water make concrete more dense. This is partly due to swelling of cement particles and partly to infiltration of impurities. Bacteria in water have also improving effect on concrete pipes even when they are made from lean mixtures such as 1:10.—A. E. BEITLICH

ENGINEERING DESIGN

BRIDGES

Test of a reinforced concrete bridge. M. LANOS. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930. Abstracted from translation in *Concrete Constr. Engr.* (England), Oct., 1930, V. 25, No. 10, p. 569-571.—Tests were made to determine effect of impact on a bridge carrying Rue Lafayette over lines of the Compagnie de l'Est in Paris. Deflections were measured for various members of the bridge. Readings were taken with loads passing over bridge at different speeds. The general conclusion drawn from the tests showed that, in bridges of this type, speed and shock do not sensibly increase stresses in principal beams. On the other hand, they produce stresses greater than those calculated in the cross girders, stringers, and the slab below the roadway.—JOSEPH MARIN

Design of road bridges. C. S. CHETTOE. *Rds. Rd. Constr.* (England), Oct. 1, 1930, V. 8, No. 94, p. 332.—Surface finish: If concrete bridges are faced with brick or masonry, dowels are not necessary, provided facing is suitably toothed into concrete backing. In exposed concrete face work, finish may be produced by use of colored cement, or special aggregates. Such facing is usually

only a few inches thick, and separated from the main body of concrete by a metal shutter, lifted as concreting operations proceed. Both kinds of concrete set together and become monolithic. Use of colored cement blocks avoids risk of patchiness. When special aggregate is used, it is usually crushed local stone. The surface skin of cement has to be removed, by some suitable method such as bush hammering or scrubbing with a wire brush or use of chemicals. The molds may also be coated with special retarding solutions, so that the surface easily brushes off with scrubbing. Further effects may be obtained by polishing with carborundum, or painting with waterproof paint.—JOHN E. ADAMS

Reinforced concrete canal bridges in Belgium. M. BOUCAU. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930. Abstracted from translation in *Concrete Constr. Eng.* (England), Oct., 1930, V. 25, No. 10, p. 561-563.—To conform with clearance necessary for the passage of barges and with topography of the land, the depth of construction available was only 2 ft. 10 in. in one case. A concrete arch bridge would not permit sufficient clearance and a steel bridge would be too costly. A satisfactory solution was found by constructing a portal with hinges at low level.—JOSEPH MARIN

BUILDINGS

High buildings of steel or concrete? K. SCHAECHTERIE. *Teknisk Tidskrift* (Sweden), Sept., 1930, No. 9, p. 124-126.—An office-warehouse building, five stories high and with a live load of 51½ and 206 lb. per sq. ft. for the office and the warehouse respectively was figured for cost and a comparison made between cost of a concrete and of a steel structure. The concrete building was found to have 1 per cent less effective floor area and to weigh 25 per cent more than the steel building. The cost for the former was 3.25 Mark against 3.73 Mark per sq. ft. effective floor area for the steel building, a difference of 15 per cent.—O. Albert

Design of wind bracing. EDWARD SMULSKI. *J. Boston Society Civil Eng.*, Nov., 1930, p. 491-523.—Details of the design of wind bracing are presented for tall buildings both of reinforced concrete and of steel, with particular attention to design of the connections of the wind bracing for steel structures. Reinforcement is required in concrete wind braces at the column to resist both positive and negative bending moments, the zone of negative bending moment extends further from the column than for an ordinary restrained beam and diagonal tension reinforcement may be required for the entire length of the beam to take care of the shear.—MILES N. CLAIR

DAMS

Unique cutoff construction and arched foundation features of Rodriguez dam. (See FIELD CONSTRUCTION—Dams.)

MISCELLANEOUS

Construction of quay at Rotterdam. W. F. VAN DIJCK. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930. Abstracted from translation, *Concrete Const. Eng.* (England), Oct., 1930, V. 25, No. 10, p. 557-61.—The quay walls will be 8500 ft. long and are designed to allow for an ultimate depth of water of 39 ft. Vertical walls were adopted to permit simplification in placing concrete, and though greater amounts of steel and concrete will be required than by using battered walls, the ultimate unit cost will be less. Details are given of method of construction. The layout of the yard and method of constructing caissons are points of interest. Coulomb's

method of calculating earth pressure was adopted, using values of $\phi = 30$ degrees and $\phi = 40$ degrees for sand below and above water level respectively. —JOSEPH MARIN

New railway roadbed construction of reinforced concrete. *Zement* (Germany), Sept. 18, 1930, V. 19, No. 38, p. 904-5.—A new type of foundation for railroad tracks is described, which can be used with great advantage for railroad bridges where vibrations of structure must be reduced to minimum. Tracks are connected to concrete foundations by means of heavy steel springs. Experiments undertaken on main line of Austrian railroad gave excellent results. (cf. Wirth, *Organ f. d. Fortschritte d. Eisenbahnwesens* (Austria), Nov. 1929, No. 21.)—A. E. BEITLICH

Concrete retaining walls. E. W. ANDREWS. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liège, 1930. Abstracted from *Concrete Constr. Eng.* (England), Oct., 1930, V. 25, No. 10, p. 572-573.—Cross sections and relative economies of plain and reinforced concrete walls designed to fulfill as nearly as possible the same conditions for three different forms of construction and two different theories of earth pressure are discussed. The three forms of construction are: (1) mass concrete, (2) "slightly" reinforced concrete, and (3) "conventional" reinforced concrete.—JOSEPH MARIN

Examples for calculation of reinforced concrete structures. "Exemples de calculs de constructions en beton arme." LEON COSYN. Editor: Librairie Politechnique Ch. Béranger, Paris and Liège (Belgium), 1928, 3rd edition, Fr. 60.00. Reviewed in *Zement* (Germany), Sept. 4, 1930, V. 19, No. 36, p. 858.—Book is continuation of: "Practical treatise of reinforced concrete structures" (Traité pratique des constructions en béton armé) by same author. Fundamental principles of calculations, which arise in all fields of reinforced concrete construction are discussed and explained with numerous examples. In its seven parts, book deals with scaffolds; prismatic structural parts exposed to compression, tension, flexure or torsion; discussion of total structures, and gives tables for use by designer and contractor.—A. E. BEITLICH

Parabolic sheds in reinforced concrete. L. BAES AND J. VERDEYEN. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liège, 1930. Abstracted from translation in *Concrete Constr. Eng.* (England), Oct., 1930, V. 25, No. 10, p. 563-565.—These sheds are used for storage of chemicals of a highly cohesive nature. Products of this kind cannot be stored in ordinary silos. Experience has proved that best cross section is parabolic or nearly so. A three hinged arch was used. Economical ratios between rise and span are given and dimensions and details of construction are outlined.—JOSEPH MARIN

Shaping of incomplete reinforced concrete hinges. ALEX JESINGHAUS AND OTTO BIELIGK. *Zement* (Germany), Sept. 4 and 11, 1930, V. 19, No. 36-37, p. 850-5, 873-9.—Critical study was made investigating influence of shaping of joints and placing of steel in reinforced concrete hinges. Mathematical calculations illustrate occurance of stresses in hinges of different shapes and with different reinforcements. Certain types are discussed and their application and advantages characterized. Great care must be taken in placing steel reinforcements, number of which should not exceed the necessary limit, so that uniform concreting can be done.—A. E. BEITLICH

Oregon highway bridge to be built by Freyssinet arch method. *Eng. News Record*, Aug. 21, 1930, V. 105, No. 8, p. 290.—Utilization of Freyssinet system of concrete arch construction will be feature of major interest in building Rogue River highway bridge now under construction for Oregon State Highway Commission. Seven pairs of arch ribs each having 222-ft. span and

rise of 47 ft. make up main portion of structure. At either end will be 144 ft. of concrete viaduct approach composed of 16-ft. arches, making a total length of 1,938 ft. Abutments at ends of main arch system will rest on rock and those for six intermediate piers, including two abutment piers, will rest on foundations of piles driven in gravel. Intermediate abutment piers divide arch system into a three-span group and two two-span groups on either side. The piers are designed as yielding or elastic, believed to be an innovation in use of Freyssinet method. In this method rib-shortening and shrinkage stresses are reduced by leaving an opening at crown of each rib in the concrete and inserting hydraulic jacks to allow for adjustments. These jacks permit the position of the arch to be maintained or corrected, following the construction period, until sufficient time has elapsed for rib-shortening to take place. Because of unusual design, the structure is to be a cooperative research project with U. S. Bureau of Public Roads and State of Oregon as participants.—D. E. LARSON

Design of road bridges. C. S. CHETTOE. *Rds. and Rd. Constr.* (England), August 1, 1930, V. 8, No. 92, p. 257; No. 93, p. 297.—Retaining walls: Mass concrete walls, rarely employed for greater heights than 10 ft., should be battered slightly to care for settlement under the toe. Rankine's Theory is still mainly used, and is applied to stability against sliding and overturning. Respective factors of safety should be 1.5 and 2.0. For live load, a 3 ft. surcharge is usually satisfactory to cover effect of Ministry of Transport train. All walls should be backed with dry fill, and provided with weepholes. It is essential that concrete in the toe of wall be formed against virgin soil, without fill, and that no open drain be constructed in front of wall. Otherwise passive pressure will be destroyed and sliding result. For reinforced concrete walls up to 12 ft. high, L-walls without counterforts, consisting of vertical slab, toe and heel are common. The resistance to sliding may be increased by sloping the footing slab. If the toe is much greater than the heel, to avoid excessive cutting into the bank, the stability factor is lessened, but by making the footing slab butt against the road slab, good resistance against sliding is provided. For heights greater than 10 to 12 ft. counterforts with horizontally spanning slabs are more usual. Positive moments are taken as $\frac{pl^2}{24}$ and negative moments over the counterforts as $\frac{pl^2}{12}$. Expansion joints should be provided at 60 to 80 ft. centres. Spandrel walls should be provided with sufficient joints to avoid restraint of freedom of movement of arch. Details of suitable reinforcement are also given. Criterion of allowable foundation pressure is maximum settlement allowable, and difference of settlement between one abutment and another. For any appreciable settlement a three-hinged arch or a free span should be used. For weak ground, caissons, i. e., steel or concrete vertical cylinders with cutting edges may be used. Skin friction may be allowed for, when a good foundation does not exist at reasonable depth. Timber piles are only to be recommended when under water for their entire length. The Engineering News Formula, is quoted. Details of typical reinforced concrete piles are given, and the Dutch Formula for driving is quoted. General descriptions of the best pile group arrangements in various types of bridges are described.—JOHN E. ADAMS

WATER WORKS

Reservoir at Barming, Maidstone. *Concrete Constr. Eng.* (England), Oct., 1930, V. 25, No. 10, p. 543-549.—The reservoir is an extension of one already existing and is being constructed as close as possible to the existing structure. It is designed to withstand the stress due to either structure being

full of water. Details are given of the design and method of construction of retaining wall, floor and roof.—JOSEPH MARIN

ARCHITECTURAL DESIGN

Colored architectural concrete in large country residence. JOHN K. BRANNER. *Concrete*, Oct., 1930, V. 37, No. 4, p. 23.—Dutch Colonial type of architecture and use of colored concrete in exterior of building and on grounds are features of Woodside, California, residence built for cement company head. House is on a hill, and between two wings there is a court facing a formal walled garden containing orange trees. Reinforced concrete gable walls rise above the roof, and are ornamented with scrolls of Dutch character. Floors are of structural concrete, laid on light fabricated steel joists and surfaced with oak and teakwood nailed to furring strips in the concrete. Roof is covered with dark grayish brown shingle tile. Colored concrete is used in floor of the enclosed court, laid out in checkerboard design in black and white. Balcony above court is supported by white concrete columns.—C. BACHMANN

Concrete plastics in Afghanistan. DAHL. *Zement* (Germany), Sept. 11, 1930, V. 19, No. 37, p. 880-2.—Preparation of ornamental plastics for new City of Dar-ul-aman in Afghanistan was very difficult because of lack of suitable stone materials. Quarries of European type are practically unknown in this country. Stones are seldom longer than 24 in. or wider than 6 in. and cannot be used for greater sculptures. Faced by these conditions, architect and artist Karl Maas undertook difficult task of producing desired plastics of concrete. Clay and gypsum for molds were difficult to obtain and the latter had to be burned in small wood-fired furnace. Cement was furnished by new cement plant in Kabul. Aggregates were carefully washed and prepared. Among the many plastics may be mentioned a fountain, ornaments and pillars of royal castle in Kabul. Plaster technique is well known in Afghanistan where kind of clay-stucco is used. Very old samples of their primitive art are still preserved.—A. E. BEITLICH

FIELD CONSTRUCTION

BRIDGES

Mid-Hudson bridge paved in alternate slabs to equalize cable loads. *Eng. News Record*, Oct. 9, 1930, V. 105, No. 15, p. 581-582.—Dead load stresses on the suspension cables supporting the Mid-Hudson bridge at Poughkeepsie, N. Y., were equalized during laying of concrete by carefully planned sequence of field operations. Concrete roadway across the 3,000-ft. structure is 30 ft. wide between curbs and 8 in. thick, heavily reinforced with built-up mats of ½-in. steel rods. This pavement, together with two 4½-ft. concrete sidewalks 3 in. thick, imposes a dead load of 4,000 lb. per linear ft. on the bridge. Concrete was laid in three strips, the center one being 9 ft. 4 in. wide and the two side strips each 11 ft. 1 in. wide. An industrial railway was used to deliver mixed concrete and to handle forms and steel. The center strip was first completed by working from center toward both ends of bridge simultaneously. The narrow-gage track was then shifted to the finished slab and paving again started from middle. In this case, however, alternate panels of the two outside roadways were poured, first on one side of center strip and then on other, leaving staggered gaps. These openings were then filled alternately so that during the whole paving operation weight of roadway was distributed uniformly between cables.—D. E. LARSON

The "Albert Louppe" bridge of reinforced concrete. A. COYNE, E. FREYSSINET. *Genie Civil* (France), Oct. 4, 1930, V. 97, No. 14, p. 317-334.—The bridge, recently completed, consists of three reinforced concrete arches of 566.13 ft. net opening each, crossing the Elorn some four miles out of Brest. The very long spans are the feature of this structure and were adopted, after much debating, to reduce number of piers and consequently the delays and hazards inherent in maritime construction. After laboratory tests of locally available quartzite deposits, this material was approved for concrete aggregate. Experience on the job, where erratic results were frequently obtained, proved it advisable to add a certain proportion of dune sand, which was fixed at 50 per cent on the basis of tests. This sand acts as a lubricant and corrects the grading, increasing the proportion of fines. This method proved extremely practical and did not increase the costs. Field tests were made on 8-in. cubes. No especial care was given to the making of the specimens, so that the results may be considered as minimum values. Concrete in the arches was subjected to mechanical vibration in large masses, and is naturally far superior to that of the specimens tested. The following strength values were obtained on test cubes of the five grades of concrete used: Grade 1 (used in approaches), 2600 lb. per sq. in. at 7 d.; 3620 lb. per sq. in. at 28 d. and 5400 lb. per sq. in. at 1 yr. Grade 2 (used in approaches, apron, arches), 3500 lb. per sq. in. at 7 d., 4480 lb. per sq. in. at 28d. and 6300 lb. per sq. in. at 1 yr. Grade 3 (arches), 3860 lb. per sq. in. at 7 d., 5000 lb. per sq. in. at 28 d. and 6650 lb. per sq. in. at 1 yr. Grade 4 (foundations in sea water using fused cement, i. e., ciment fondu), 3180 lb. per sq. in. at 1 d., 4310 lb. per sq. in. at 7 d. and 4940 lb. per sq. in. at 1 yr. Grade 5 (foundations in sea water, ciment fondu), 4030 lb. per sq. in. at 1 d., 4810 lb. per sq. in. at 7 d. and 5190 lb. per sq. in. at 1 yr. The proportions by volume varied in the five grades as follows: 0.9 to 1.04 cu. yd. gravel, 0.5 to 0.65 cu. yd. of sand and 660 to 880 lb. of cement. The "Abrams cone" or slump test was used, the slump being 5.9 in. for portland cement specimens and slightly greater for fused cement. This test, however, loses its importance when the concrete is worked by vibration, as resultant settling is independent of quantity of mixing water. The portland cement used in 1:3 mortar had a compressive strength at 7 d. of 3080 lb. per sq. in. and at 28 d. of 3860 lb. per sq. in. The 1:3 mortar of the fused cement had a compressive strength at 2 d. of 3900 lb. per sq. in.; at 7 d. of 4320 lb. per sq. in. and at 28 d. of 4550 lb. per sq. in. A total of 32,500 cu. yd. of concrete was placed on this job, requiring a total of over 1600 tons of steel reinforcement and about 2600 cu. yd. of forms.—M. A. CORBIN

New Wandau bridge over river Enns (Austria). JOSEF KREBITZ. *Zement* (Germany), Oct. 9, 1930, V. 19, No. 41, p. 964-7.—Old wooden bridge was replaced by single span concrete arch bridge crossing highway, river and railroad. Main span over river valley is 242 ft. long, center being 50.8 ft. above normal water level. Arch is 16.4 ft. wide at center and increases to 23 ft. wide at abutments; its thickness varies from 2.6 ft. at center to 4.6 ft. at abutments. Some steel reinforcement was necessary at center and abutments only, since arch is so designed that only compressive stresses occur. Two prismatic concrete columns, 23.6 ft. wide and 6.5 ft. thick, are at ends of arch. Openings for highway and railroad are 32.8 and 45.3 ft. wide and 30.5 ft. high. Abutments consist of mass concrete foundations on solid rock. Roadway has inclination of 1 per cent; it is 16.4 ft. wide at center of arch and 19.7 ft. and 20.7 ft. wide over side openings. Reinforced concrete flat slabs, 16.5 in. thick with top layer of bituminous material, were used for its construction. Concreting was carried out in 31 sections, divided by joints 11.8 in. wide. Aggregates of high quality were found in neighborhood of construction site. All invisible concrete surfaces were finished with a coating of Inertol to prevent penetration of water.—A. E. BEITLICH

Reinforced concrete arch bridge over the river Rench in Erlach, Baden (Germany). H. GLOCKNER. *Zement* (Germany), Aug., 1930, V. 19,

No. 33, p. 782-4.—Old highway bridge, which was insufficient for increasing traffic was replaced by concrete arch bridge with span of 67 ft. Abutments of old bridge were used for new structure. Roadway, which is of suspension type, is 17 ft. wide and consists of 7.8 in. thick continuous reinforced concrete slab which is supported by 13 horizontal beams. These are 11.5 in. wide and 19.7 in. high and are placed 4 ft. 9½ in. apart. Cross-section of arches is 32.3 in. by 21.6 in. Two horizontal beams which are 16 in. wide and 19.7 in. high connect centers of both arches. Bridge crosses river at angle of approximately 76 degrees, 61 ft. above high water level. High early strength portland cement was used for arch construction while road slab was made of ordinary portland cement. Special care was taken for exact proportioning of aggregates which were sieve analyzed at site. Mixture (1:5) consisted of 1.5 parts gravel of 1⅜ in. size, 1 part gravel of ⅝ in. size, 2.5 parts sand and 1 part cement. Strength properties of cement and concrete were carefully examined during entire construction period.—A. E. BEITLICH

BUILDINGS

Transformer station in Nuernberg (Germany). G. PFEIFFER. *Zement* (Germany), Sept. 4, 1930, V. 19, No. 36, p. 855-8.—Building is five-story skeleton structure of reinforced concrete made exclusively of high early strength cement. It contains four transformer units. Foundation consists of one continuous reversed Pilz-slab, which is from 19.7 to 23.6 in. thick and strongly reinforced. Floors of superstructure were constructed for loads of 573, 471 and 164 lb. per sq. ft. Provisions were made for two additional stories on top when enlargements are necessary. These are designed for 123 lb. per sq. ft. each. Interesting construction details are given.—A. E. BEITLICH

Modern park structures in Frankfurt a. M. (Germany). CRAEMER. *Zement* (Germany), Sept. 25, 1930, V. 19, No. 39, p. 920-2.—Building which serves as an open air restroom was constructed of reinforced concrete. Flat ceiling was made as Pilz-construction with thickened center portion. Projecting part of ceiling rests on four reinforced concrete columns. Concreting was done in planed forms; no finishing was necessary. A second structure of similar construction is described.—A. E. BEITLICH

New forming methods for small concrete buildings. F. SCHNEIDER-ARNOLDI. *Zement* (Germany), Sept. 25, 1930, V. 19, No. 39, p. 922-4.—A building material with almost ideal properties for small building construction is light concrete with pumice or tufeceous materials as aggregates. Only disadvantage is price of forms which is too high compared with relatively small volume of concrete. Improvements were made by using certain standard forms for building parts, which were built very often. A new type of forms is described. Wire nettings are mounted on iron frames and are used instead of wooden forms. In order to keep exact distance between two sides of these wire forms, connecting links are placed between them. Concrete is poured with plastic or earth-moist consistency. Great care must be taken to keep concrete wet during setting period, since open wire meshes allow faster evaporation of mixing water, especially in warm weather. Amount of concrete which falls through meshes is very small. Distribution of concrete in forms can be easily controlled. Openings of the meshes are about 0.6 to 0.8 in. and thickness of wire is between 0.039 and 0.060 in. No finishing of concrete surface is necessary. —A. E. BEITLICH

Concrete distributed by two towers connected by adjustable chute. *Eng. News Record*, Oct. 23, 1930, V. 105, No. 17, p. 661.—Use of a chute suspended from a high line between two towers at opposite ends of a long theatre building was the economic solution of a concrete distribution problem

encountered in Beverly Hills, Calif. A small corner lot which dictated the location of the concrete plant at the inside rear corner and a high tower section at front of building necessitated this unusual arrangement. The building is 230 x 130 ft. in plan and 78 ft. high except for front section, which is 120 ft. high. Near the concreting plant a hoisting tower 247 ft. high was erected. From this point it was necessary to distribute concrete to the front corners of the building 250 ft. distant. A 187-ft. secondary tower without hoisting equipment was erected near the front of the building. The two towers were connected by a 1-in. cable which supported a 12-in. metal chute on a 1:3 slope. Secondary chutes extending from the towers enabled concrete to be distributed to all parts of the structure.—D. E. LARSON

Corrosion of structural steel. (See PROPERTIES OF CONCRETE.)

DAMS

Mersey river hydro development. CLIVE W. CURRIE. *Canadian Eng.*, Sept. 30, 1930, V. 59, No. 14, p. 501.—Nova Scotia Power Commission has completed and put in operation three developments on the Mersey River, at Upper Lake Falls, Lower Lake Falls and Big Falls, with a combined output of 28,000 h. p. at minimum head. Upper Lake Falls development consists of an earth fill dam with concrete core wall, 49 ft. high and 1600 ft. long with concrete spillway 250 ft. long. At Lower Lake Falls one mile below an earth dam with concrete core wall 4000 ft. long was built. Concrete spillway section is 850 ft. long. Dam at Big Falls is also of earth with concrete core wall with concrete spillway section 600 ft. long.—G. M. WILLIAMS

Unique cutoff construction and arched foundation features of Rodriguez dam. *Eng. News Record.* Oct. 16, 1930, V. 105, No. 16, p. 600-604.—Building a cutoff wall from streambed downward as excavation was advanced through shafts and providing an arch to support four buttresses of the highest Ambursen-type dam ever built, were innovations in foundation construction used at Rodriguez dam, now under construction on the Tijuana river in Mexico. The arch span at intradosal springing line varies from 86 ft. at cutoff to 76 ft. at downstream end of structure. This decrease of span has advantage of providing wedge action which increases resistance to sliding and places heaviest buttress loads over shortest span. Arch rise varies from 28.2 ft. at cutoff to 32 ft. at other end of 225-ft. length of arch barrel. Arch barrel is designed to carry entire load of four buttresses to sound rock at sides. For symmetrical loading, crown of arch was placed halfway between two buttresses. Final arch computations including rib shortening and shear distortion, proved entire arch to be in compression and no bending reinforcement was used. Heavy reinforcing parallel to and directly under each buttress provides for any lateral bending in the arch. Maximum design stress for concrete was 700 lb. per sq. in.—D. E. LARSON

The Perak river hydro-electric power scheme. *Engineer* (England), Aug. 22, 1930, V. 150, No. 3893, p. 191.—Perak River Hydro-Electric Power Co., has built a hollow reinforced concrete dam of the Ambursen type on the Perak River in the Federated Malay States, forming a storage reservoir having an area of about 10 square miles with a catchment area of 2350 sq. miles. Dam was built slightly curved upstream to take advantage of good rock foundation. Spillway section furnishing a head of 63 ft. at low water, has a total length of 684 ft. and is divided into two sections by a sector gate with free opening of 100 ft. situated between piers near the center of the river. Spillway section consists of reinforced concrete slabs forming a continuous deck on upstream and downstream faces, supported by reinforced concrete buttresses 18 ft. on centers based with horizontal concrete struts in every second bay. Slabs are held in place by offsets and notches in buttress heads. Vertical contraction joints are

provided at each buttress and horizontal joints are arranged at intervals of 16 ft. between each section of the slabs. On the left bank the dam changes to the solid gravity type with same spillway curve as hollow section. This section was poured with vertical contraction joints extending down to rock foundation at 30 ft. intervals. River bed below dam is protected from scour by reinforced concrete aprons extending 100 ft. downstream.—G. M. WILLIAMS

MISCELLANEOUS

Wagon for distributing ready mixed concrete. *Engineer* (England), May 23, 1930, V. 149, No. 3880, p. 584.—The "Sentinel" Waggon Works, Ltd., is constructing a wagon for distributing ready mixed concrete. The mixer drum with a capacity of 5 cu. yd., is cylindrical in section with a conical discharge end, and is filled with internal blades. Drum is mounted on a double-geared, tipping model steam wagon, with tipping gear operated by an oil pump. The drum revolves at 10 to 20 r. p. m. either when the vehicle is in motion or at rest. Two tanks mounted above drum carry water, one for supplying water for the mix and the other for flushing the drum after discharge. In operation, weighed cement and aggregates are loaded into drum through the apex of the conical end, proper amount of mixing water is sprayed in, and mixer drum is rotated about 5 minutes before arrival at destination.—G. M. WILLIAMS

New experiences in American and German concrete construction practice. LUZ DAVID. *Zement* (Germany), Aug. 7, 1930, V. 19, No. 32, p. 750-5.—Author discusses opinions and experiences of American investigators on manufacture of concrete, which were presented at annual meeting of American Concrete Institute in 1930. Special discussion is given of methods for manufacture of ready mixed concrete. Advantages and disadvantages of central plant mixed concrete and central plant proportioned truck mixed concrete are characterized. Cost calculations are given for economic installation and maintenance of ready mixed concrete plants. Second part of article deals with experiences in winter jobs. Heating and protecting methods for raw materials and finished concrete are illustrated. Calculation and design of reinforcement must be made subject of more careful consideration.—A. E. BEITLICH

Cooling tower at Croydon. *Concrete Constr. Eng.* (England), Oct., 1930, V. 25, No. 10, p. 555-57.—The most interesting feature from the point of view of construction is the arranging of the scaffolding for these hyperbolic cooling towers. The ultimate cost of the work largely depends on the scaffolding.—JOSEPH MARIN

Bonding new concrete to old. *Engineer* (England), Oct. 10, 1930, V. 150, No. 3900, p. 393.—The Department of Scientific and Industrial Research has conducted experiments to determine what precautions must be taken to insure a good bond between old and new concrete with the following results: (1) Laitance which forms a porous, chalky mass of non-coherent material must be removed. (2) If concrete is more than four hours but less than three days old the surface should be wire brushed and washed after removing laitance. (3) A ½-in. layer of mortar, without coarse aggregate, of the same composition as the new concrete should be applied before the new is placed. (4) If the concrete is more than 4 days old the surface should be chipped away, brushed and rinsed. This is followed by a slurry of neat cement, then a layer of mortar as in (3) before placing new concrete.—G. M. WILLIAMS

Full circle section of 17-foot tunnel lined in single pour. *Eng. News Record*, V. 105, No. 16, p. 610-612.—Cushman No. 2 tunnel, 13,000 ft. long and 17 ft. inside diameter, is located on the Olympic peninsula about 70 miles northwest of Tacoma, Washington, and will convey water from the Skokomish River through a spur of Olympic Mountains to develop a static head of 475 ft.

on hydraulic turbines of a 75,000-kw. plant at tidewater. A special tunnel form with pneumatic placing makes it possible to concrete full circle of lining 17 ft. in diameter and 40 ft. long in continuous operation. With this method of placing, copper water stops are required only in circumferential joints at 40-ft. intervals. The carriage for steel forms consists of two 5-ft. steel girders, 83 ft. long, supported on four end posts consisting of 8-in., H-section steel columns. Each girder carries along its upper flange a row of flanged wheels serving as rollers on which the circular steel form is advanced along the carriage when being moved ahead to new position. The cylindrical steel form is so constructed and hinged that it is readily collapsed for moving ahead and then expanded into position for placing concrete. All concrete is put into place by means of a 2-cu. yd. pneumatic concrete gun with a 6-in. delivery pipe about 80 ft. long. Thickness of concrete lining is specified as 15-in. average with 8-in. minimum.—D. E. LARSON

Selling concrete right from the mixer. *Concrete Products*, Oct., 1930, V. 39, No. 4, p. 30-33.—The J. L. Shiely Co., producer of sand and gravel and crushed stone, St. Paul, Minn., has developed two plants for production of ready-mixed concrete. One plant adjoins sand and gravel plant and the other adjoins crushed stone plant, each one using material in which it is in close touch. A definite guarantee is made by the company to deliver a mix of specified strength; as for instance 1,500 lb. per sq. in. in 28 days for a 1:3:5 mix; 2,000 lb. for a 1:2:4 mix; and 2,500 lb. for a 1:2:3½ mix. The delivered prices for 1:2:4 concrete, which is mix used on most jobs (guaranteed to have a strength of 2,000 lb. at 28 days) is from $8.00 to $9.05 per cu. yd. on less than 100 yd. orders, depending on zone or distance from the plant. The 1:2:3½ concrete (2,500 lb. per sq. in. strength) is 15¢ per yd. more, and 1:3:5 concrete (1,500 lb.) is 75¢ per cu. yd. less. Orders of more than 100 cu. yd. carry prices 50¢ per yd. lower than those given on the price list. Heating in winter is charged for at rate of 40¢ per cu. yd. A discount of 5 per cent is allowed for cash or payment by tenth of the following month.—E. S. HANSON

Railroad box car with haydite concrete floor. *Rock Products*, June 7, 1930, V. 33, No. 7, p. 74.—Universal Atlas Cement Co., Buffington, Ind., has tried out a steel box car with a floor of haydite concrete. It has been found to have advantages over wooden floor for shipment of bulk cement, as power shovel or scraper works better on cement than on wood. The car was in a smashup which sheared the king pin of one truck but the floor was not injured. Floor concrete mix was 1 sack cement, 2 cu. ft. coarse haydite and 2 cu. ft. fine haydite. It was put on 4 in. thick but not anchored to steel floor, expansion joints and asphaltic fillers being placed between floor and sides. Round ⅜-in. reinforcing bars, spaced 6 in., running in both directions, were placed ¾ in. from bottom and wire netting was placed near top. Weight, about 36 lb. per sq. ft., or about two-thirds weight of ordinary concrete, and the cost was 35¢ per sq. ft. Advantages of the floor are greater strength than wood and better insulating qualities (when used in refrigerating cars). Disadvantages are greater weight and less nailability than wood. This is noticed with automobiles and like freight where cleats have to be nailed to bottom of cars.—EDMUND SHAW

Calibrating supports for exact centering of reinforcement. *Genie civil* (France), Sept. 27, 1930, V. 97, No. 13, p. 309-310.—The method recently invented by M. L. Ponsolle consists of small supports or clamps in the shape of a stirrup, star, disc, helix, etc., which are used on vertical and horizontal reinforcement alike and serve to keep the right distances between reinforcement and forms, as well as between individual parts of reinforcement. The method is successfully applied on a building under construction at Angers. Supports are made of very resistant metal which will withstand effect of working concrete, will not rust, and are furnished at moderate cost.—M. A. CORBIN

Concrete pipe testing machine. *Engineer* (England), Sept. 19, 1930, V. 150, No. 3897, p. 323.—A pipe testing machine has been made by Wm. Grice and Sons, Ltd., Birmingham. It consists of a platform built of steel sections mounted on four wheels. A hydraulic cylinder and ram, carrying a crosshead, is mounted on two steel columns. The ram and cross head are adjustable on the steel columns for any diameter pipe up to maximum specified. Load is applied through a hydraulic ram and pressure registered by means of a gauge.—G. M. WILLIAMS

Ferry on Lake Constanz between Constanz and Meersburg. THEODOR LUTZ. *Bautechnik* (Germany), May 9-23, and June 6, 1930, V. 8., No. 20-22-24, p. 259-9, 326-30, 350-3.—Difficulties were encountered during construction of harbors in Constanz and Meersburg. Quay is built of reinforced concrete. Three rows of concrete poles 12.6 in. square and 24.6 ft. long were driven. Poles of outer row are connected by dovetailed reinforced concrete piling. Piles are 23.2 in. wide, 6.3 in. thick and 20.7 ft. long. Distance between poles is 22.3 ft., and 4.9 ft. where expansion joints were placed. On this pile foundation rests reinforced concrete slab, 7.2 ft. wide, 2.5 ft. thick and about 328 ft. long with concrete railing on one side. Concrete piles were made at site of construction. Detailed description is given of arrangement of reinforcements, concrete mixtures, concreting and finishing of concrete.—A. E. BEITLICH

Attaining low cost in mixing and placing. CHAS. C. MOODY. *Concrete*, Nov., 1930, V. 37, No. 5, p. 23-24.—Office building for Inland Co., at Indiana Harbor, Ind., a 2000 cu. yd. job, with very low cost limits, was laid out and equipment provided. Concrete was divided into two parts: 500 cu. yds. in foundations and foundation walls, and 1,500 in the floor slabs. Sand and stone had two prices, one based on team delivery; the other on delivery by cars alongside of the building. Latter price was 35¢ per cu. yd. less. Delivery track was about 150 ft. from center of building. Crane with boom having drift of 40 ft., by which aggregate could be unloaded and dumped into hopper was available. Seventy feet remained between the hopper and building. Raising aggregate hopper from ground slightly higher than usual made it possible to place mixer closer to hopper and chute the mix directly into the hoist bucket, eliminating wheeling entirely. Hopper was put on extension legs sufficiently high to permit dropping the aggregates directly from measuring bins into mixer. Total labor cost was $104 each eight hours, and the average unit cost was close to 70¢ per cu. yd. Previously estimated cost of the concrete was about $1.50 per cu. yd., giving a total saving of about $1,600, from which were deducted cost of equipment handling. Total cost of concrete was thus only $1.19 per cu. yd.—C. BACHMANN

Finds pre-mixed concrete field made to order for gravel producers. *Pit Quarry*, Sept. 24, 1930, V. 20, No. 13, p. 58-60.—Keefner Concrete Co., Des Moines, Ia., has new ready-mix plant which utilizes aggregates procured, from the Des Moines River, by Hawkeye Co-operative Sand & Gravel Assn. which occupies an adjoining property. A drag scraper brings material from river bed into a sump whence it is pumped to the screen in the tipple. After washing and screening, the products are stock-piled. Beneath the stock-piles is a tunnel belt conveyor which delivers to an elevator which, in turn, delivers aggregates to respective sections of main hopper. Gravel batcher has a large dial scale with a dash-pot feature. Mixer is a 2-cu. yd. tilting unit. Concrete is delivered in bathtub bodies.—A. J. HOSKIN

Sioux City ready-mixed concrete plant was built for winter service. *Pit Quarry*, Sept. 24, 1930, V. 20, No. 13, p. 41-43.—Plant of L. G. Everist Co., Sioux City, Ia., is prepared to heat concrete in the winter season, loading it into delivery trucks at average temperature of 75° F. Live steam at a pressure of 50 to 60 lb. is fed into aggregates hopper above mixer through pipe with many holes. Water for concrete also is heated by a steam coil to a temperature of 180° F. When it does not pay to fire a steam boiler, oil-jet burner directs its

flame into mixer through a hole in charging chute. Cement bags are hand-trucked from cars, lifted by belt conveyor to batching platform, and emptied into batching hopper as needed. Bins for sand, gravel, and crushed stone discharge by gravity into batching hopper through lever-operated gates. Weighing is done with a 2-beam scale. Water is measured by a 100-gal. volumetric syphon tank. Concrete is dumped from 2-cu. yd. mixer directly into delivery trucks having bathtub bodies.—A. J. HOSKIN

Concrete units replace damaged brick-work in bridge pylons. *Concrete*, Oct., 1930, V. 37, No. 4, p. 17.—Walls of pylons on railroad viaduct, built 8 years ago with common clay brick in shape of hollow square and faced with Benedict stone, showed outward bulge due to expansion of brick backing, and replacement was necessary. First step was careful removal of cast stone top and facing. Material was lifted off with derrick, set on sidewalk, and carefully cleaned. In the meantime, brickwork was torn down and base of pylon cleaned. The 8 by 8 by 16-in. hollow concrete back-up units were set in 1:3 portland cement mortar, tempered with hydrated lime. Laboratory report on Van Houten units showed average absorption of 8.43 per cent; compressive strength of 1,280 lb. per sq. in. over the gross area and 2,040 lb. per sq. in. on the net area. Field test of clay unit showed absorption of 18.14 per cent.—C. BACHMANN

Nashville ready-mixed concrete plant stores combined aggregates. *Pit Quarry*, Sept. 10, 1930, V. 20, No. 12, p. 43-44.—Nashville Ready-Mixed Concrete and Supply Co., Nashville, Tenn., has plant with daily capacity of 400 cu. yd. New improvements will enable storage of six grades of aggregates in bins above mixers. Aggregates are handled by cranes to a hopper which feeds two bucket elevators, discharging into any of six compartments in a 250-ton steel bin. Bulk cement is unloaded to a ground hopper feeding a bucket elevator to a 2-compartment steel storage bin. A screw conveyor feeds from this bin to two 1-cu. yd. mixers. For one of the mixers, gravel is weighed in a 1-ton-capacity batcher, sand is measured in a 28-ft. inundator, and cement is weighed in a 1,000-lb. batcher. Materials drop into mixer hopper ready for next batch. Water is supplied from a tank alongside inundator. For other mixer, sand and gravel are handled by a 2-ton-capacity weighing batcher, cement by a 1,000-lb. weighing batcher, and water by a measuring tank. This second mixer prepares also lime mortar and cement mortar. Concrete and mortar are delivered in eight 3-ton trucks with agitator bodies.—A. J. HOSKIN

Delivering 60,000 cubic yards of centrally mixed concrete in month. R. P. BROWN. *Concrete*, Oct., 1930, V. 37, No. 4, p. 19.—Warner Co. of Philadelphia has established Central-Mix Concrete (CMC) as high standard by careful attention to all factors, including dependable delivery. Agitator type was decided best method of transporting and 15 four cu. yd. Clinton trucks were purchased at start. Fleet now comprises 85. Feature of equipment is reduction of entrained air. Unit consists of cylindrical tank horizontally mounted on truck chassis by trunnion bearings at both ends. Cylinder is kept constantly revolving so long as it carries concrete, by means of separate motor, there being no blades or paddles. "Certified concrete" is also furnished. Certification is made by independent testing and inspection company having absolute control of mix, checking of proportions and setting water tank. Inspector is stationed at each mixer, and verifies every batch. Inspection force checks sand and gravel at each mixer four times daily. At start of every job where "certified concrete" is furnished, inspection staff makes a set of not less than 6 standard cylinders and breaks them at 7 and 28 days. At Berks Street plant, sand and gravel are unloaded from barges to stockpile over tunnel feeding a 36-in. rubber belt conveyor which takes material to storage bins over mixers, which in turn feed measuring hoppers. Cement is purchased in bulk. One and one-half minutes mixing time is specified. Two Ransome 2-yd. mixers and one 3-yd. Smith tilting mixer are in constant operation being cap-

able of turning out from 1,500 to 1,800 cu. yds. daily. Orders are received over direct wire from main office after having been checked by engineering department. They are transmitted to concrete plant over a direct wire and to mixer control room over ticker tape, order stating mix, amount of concrete required, location of job, when delivery is to begin, and time between loads. As driver leaves mixer, his truck is sealed and drum started rotating. Product is sold either on strength basis or in accord with individual specifications. Deliveries are made on zone basis.—C. BACHMANN

Operates four pre-mixed concrete plants serving builders in St. Louis. W. E. TRAUFFER. *Pit Quarry*, Aug. 13, 1930, V. 20, No. 10, p. 39-45.—The Park Ave. plant of General Materials Co., St. Louis, Mo., is largest, with capacity of 1,500 cu. yd. daily. Its equipment includes locomotive cranes and 1-cu. yd. clamshell buckets, steel bins, screens, weighing batchers, with automatic dial scales, or weightographs, and three 2-cu. yd. mixers. Cement is added to the charge by hand from sacks. Fyler Ave. plant is the newest and all operations are mechanical with capacity of 900 cu. yd. daily. Sand and gravel are received in hopper-bottom cars and discharged into a long wooden bin with capacity of 350 carloads. Crushed stone is dumped by trucks into a concrete hopper whence it is conveyed into a section of main bin. Aggregates are delivered by conveyors to top of mixing plant and are fed, through a split chute, to two 4-compartment octagonal bins above mixers. Cement, unloaded in bulk from cars, by a power scraper, is elevated to bins with a capacity of 2,400 cu. ft. each. A screw conveyor feeds from these bins to a bucket elevator, to mixer department. Cement, sand and crushed stone are fed to two sets of weighing hoppers with dial scales. These hoppers discharge to batch hoppers of two 2-cu. yd. mixers. Clara Ave. plant resembles Fyler Ave. plant. Its capacity is 450 cu. yd. Aggregates are discharged from cars on a trestle to ground storage. Conveyors take the materials to a 4-compartment bin above the mixer. From its 4-compartment bin, cement is taken by screw conveyors to join aggregates which feed by gravity into weighing batchers which have dial scales and feed a 2-cu. yd. mixer. Branch St. plant is smallest with a daily capacity of 200 cu. yd. It has no mixers but prepares batches for mixing in transit. Aggregates are received in cars and unloaded by a crane to a 2-compartment bin with weighing hoppers. These feed to the truck mixers. Cement is received in bags which are opened into a small elevator discharging into a bin above the weighing equipment. A fifth plant is to be erected on Franklin Ave. at Twelfth St. The company operates 103 trucks.—A. J. HOSKIN

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, Oct., 1930, V. 37, No. 4, p. 31.—Assuming a stairway of the type illustrated in the layout, the problem of form work may be considered as comprising construction of two reinforced concrete stair landings at levels intermediate between floors, with three short runs of stairs connecting the landings to each other and previously built floors. Stair landings are likely to be either a slab or of light-concrete beam—and slab construction supported on reinforced concrete posts; or several edges of the landing slabs may be supported on recesses in stair enclosure wall. Faces of top and bottom risers (at the connection with the previously built floors) are several inches in from the face of the hatchway opening in the floor construction. Form work for stair landings must be built first. The soffit panel is sloping panel that forms underside of the stair run. It is the first to be placed after form work for stair landings is in position. This panel, as a unit, consists of $\frac{7}{8}$ in. lagging placed parallel to the risers, and is held by $1\frac{1}{4}$ by 4-in. cleats. Longitudinal joists are supported on 2 by 6-in. ledgers spiked to 4 by 4-in. posts. Following assembly of the soffit panel and its supports, form work consisting of stringers, beam sides and risers must be placed. On the free edge of the stair run there may be a small beam extending from landing to landing or from landing to floor. This will require a form for the sides and bottom of this beam. In the more usual case there is no

beam extending below the soffit, in which event the soffit panel extends to and beyond the edge of the stairs and only a beam side is provided. On the wall side the stair concrete is to be in contact with the wall, so that there is no room for a stringer or a beam side plank at the side of the stairway. A 2-by-8 stringer is placed against the wall, just above the risers, scabs again being nailed against the stringer to hold risers. In designing a mix for a stair run, a good plan is to use a 1:3 cement-sand mortar, or a concrete mixture with small coarse aggregates (not exceeding the ½ in. size) for that part of the slab below the steel reinforcement. The rest of the slab and the steps themselves may then be made of ordinary concrete of dry consistency. Another practice is to use small-sized coarse aggregate, either pea gravel or crushed aggregate not exceeding the ½ in. size, for all concrete in stairway work. Most convenient place to set posts and props supporting stairway form work is on newly concreted stairway and landings immediately below.—C. BACHMANN

RAILWAYS

Tokyo's underground railway. H. SAKAKIBARA. *Eng. News Record*, Oct. 23, 1930, V. 105, No. 17, p. 655.—An underground railway 8½ miles long is being constructed at Tokyo, Japan, for the Tokyo Underground Railway Co. The subway consists of a double or twin tube having rectangular steel frames of I-beams spaced 5 ft. apart and embedded in heavy walls, floor and roof of reinforced concrete. Concrete in the walls and roof was poured through chutes from a portable mixing plant on the street surface.—D. E. LARSON

ROADS AND PAVEMENTS

Concrete roads and their joints. H. C. JOHNSON. *Engineer* (England), Sept. 26, 1930, V. 150, No. 3898, p. 349.—A concrete road built in Cork, Ireland, 10 years ago and subjected to medium heavy traffic shows no defects. Section is 21 ft. wide, 7 in. thick at center and 5 in. at edges, flat base, with the edges reinforced with a concrete curb poured later but doweled to the slab, and reinforced with 2 ½-in. round bars. Transverse steel reinforcement in slab consisting of ½-in. round bars, 15-in. centers, with 7½-in. longitudinal distributing bars, is placed 2½ in. above lower surface of slab at center and rises to 2 in. from upper surface at sides. Concrete was a 20 per cent mixture, that is, 20 per cent of volume of finished concrete was cement. Slab was laid in sections 80 ft. to 90 ft. long, one half day's run with transverse shoulder or supporting lip formed by digging a shallow trench at the end of the slab. Vertical joint between slabs consists of tar paper attached to a ¼-in. thick pine strip. Concrete slab was roughly leveled with shovels, smoothed with long screed with double handles, operated transversely, followed by a light roller longitudinally, then finally by a 10-in. belt transversely.—G. M. WILLIAMS

Expansion joints in concrete. *Canadian Eng.*, Oct. 14, 1930, V. 59, No. 16, p. 544.—The Technical Advisory Committee of the Ministry of Transport of Great Britain has made a survey of defects in a recently constructed road three miles long, 30 ft. wide between curbs, built on a ballast bank varying in depth from 2 ft. to 20 ft. Wearing surface consists of 2-in. stone filled asphalt carpet on 8-in. thick reinforced concrete foundation. Concrete was laid in bays 14 ft. 6 in. wide, full width of road with no center joint, on the alternate bay system, every fourth joint filled with bituminous sheeting, with joint

supported on a 12-in. by 8-in. beam formed below. Mix was 1:2:4 by volume, ballast aggregate, with 4.7 lb. reinforcement per sq. yd. placed 2 in. from under side of concrete slab. Traffic consists of 10,000 tons per day mainly fast moving heavy commercial vehicles. After twelve months of service cracks have appeared at 14 ft. 6 in. intervals, indicating movement between adjacent slabs. Concrete has failed at the joints apparently due to depression of slab carrying load below level of adjacent slabs which in turn are struck heavy hammer blows as the load comes on. Remedy for these joint movements on newly made ground has not been definitely established but defects may be eliminated by thickening slabs at joints, or as a whole, or by the use of beams or interlocked joints.—G. M. WILLIAMS

Granili Street in Naples. LUIGI BRUSCHETTI. *L'Industria Italiana Del Cemento* (Italy), Feb., 1930, p. 20-24.—Granili St. is a concrete paved street built in 1925 which carries a very heavy traffic of iron wheel horse drawn wagons. Although some repairs have been necessary recently, concrete has generally shown little signs of wear. The author contends that the fault was in the materials or method of placing at particular points where disintegration has occurred. It is suggested that the surface of a concrete street should be made up of about 2-in. stone and cement without sand or intermediate size stone. A photograph is given showing a bridge roadway of concrete which has been in place for 22 years without deterioration.—C. G. CLAIR AND M. N. CLAIR

Results obtained by use of cement in Germany. VILBIG, MAIER, MULLER, OTZEN AND RIEPERT. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, Washington, D. C., 1930.—First concrete roads in Germany were built in 1890. Although methods of building these "cement macadam" roads differed appreciably from those in use today, many of these pavements are still in good condition. Extensive use of concrete as a paving material is limited by economic conditions. In general, this type is used only on heavily loaded roads, roads carrying a preponderance of motor vehicles and roads constructed in new locations. Two course method is preferred, using a 1:7 mix by volume in base and a 1:4 mix by volume in top. Carefully selected, durable materials are used in top and local materials in base. For bottom course, concrete has a consistency of moist earth whereas concrete in top course is somewhat wetter to facilitate finishing. Both hand and machine methods are employed but machine finishing is on the increase. Pneumatic tampers are used to consolidate base course. Steel reinforcing has recently been introduced using a 2½-in. mesh, placed about 1½ in. below surface. Slab thickness varies from 6¼ to 12 in., of which about three fourths is in the bottom course. Thickened edge sections are employed, with longitudinal joints on all roads more than 20 ft. wide. Transverse joints are spaced from 26 to 49 ft. apart, depending upon conditions and are the plain butt or open joint type, subsequently filled with asphalt. Sodium silicate has been used for hardening surface, without any marked improvement being noted. Bituminous treatments for curing have not been successful, although original laboratory results were favorable. Curing at present is by means of canvas followed by earth or straw as in the U. S. Curing period is in general from three to four weeks. Rate of progress attained in construction is variable. From 395 to 430 ft. of pavement 16½ ft. wide in 8 hours is considered good performance. Results secured using special Soliditit cement (cement to which ground silica has been added), have been good. Results may have been due to care exercised during construction. Limited results from use of Rhoubenite concrete have not been satisfactory. This concrete contains "Houben powder" an admixture. At first, concrete construction met with considerable opposition in Germany, as it was felt that there was a danger of destruction of the slab by formation of cracks and by steel tires of horse-drawn vehicles. These objections are no

longer of importance because of increase in automotive traffic. Considering the results obtained with concrete roads, the outlook for this type of construction is steadily and surely becoming better.—F. H. JACKSON

Results obtained by use of cement in Belgium. E. VAN HAUWERMEIFEN. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Cement has been used in Belgium in two forms, in concrete and mixed with stone dust to form a macadam binder. Most of the pavements have been built under the "Rhoubenite" or "Soliditit" patents, being constructed between 1921 and 1927. Maintenance was at first neglected but is being attended to much more promptly than in the past. Maintenance consists in filling cracks and joints with tar or bitumen. Light bituminous skin coats have not proved successful. Due to practice in Belgium of constructing the even numbered slabs after odd numbered slabs have thoroughly set (sometimes a period of several days elapses) it is difficult to obtain smooth riding surfaces. Author believes slabs 33 ft. long should be constructed rather than 16½ ft. which is present practice, so as to reduce number of impacts due to difference in elevation between adjacent slabs. In contrast with American practice, concrete pavements are constructed on a plane subgrade and are thickened at center. Proportions are controlled very accurately, coarse aggregate being measured in 3 sizes. Proportions now required are as follows: 1000 lb. portland cement, 12½ cu. ft. of sand, 9 cu. ft. stone chips, .08 to .2 in. in size; 10½ cu. ft. stone chips, .2 to .8 in. in size; and 21 cu. ft. crushed stone, .8 in. to 1.6 in. in size. A relatively dry mix is used and the concrete is consolidated either by rolling followed by hand tamping or by mechanical tampers. Construction is in two courses. When rolling is specified, slabs are constructed continuously, otherwise alternate construction is employed. Curing is done by covering with sandy soil kept moist for 25 days. Specifications require that the concrete develop a crushing strength of 5650 lb. per sq. in. at 56 days. Tests are made on 4-in. cubes sawed from 16 in. by 16 in. blocks which are chiseled out of the pavement. A penalty is exacted for failure to obtain this value which is calculated as follows: Penalty in francs per sq. cm. $\frac{400-X}{100}$ where X is the unit crushing strength obtained by test (expressed in kg. per sq. cm.). In order to compare the results obtained with practice in the U. S. 6 in. by 12 in. cylinders are cast alongside the road. Concrete cores are also drilled from the pavement to compare with cubes and cylinders. Approximately 124 miles of pavement has been constructed on the national roads. This type has won the unanimous approval of the road user due to its cleanliness, non-skid properties, visibility at night, etc. The one disadvantage is irregularity of surface due to difference of elevation of adjacent slabs. A satisfactory estimate of cost is difficult to obtain. It may be said in general that cost of construction is about one-half cost of block paving and about twice as much as ordinary surface treated macadam. The report includes a discussion of dry cement-stone dust mixtures as macadam binders as well as so-called mortar macadams. In latter type, a rich portland cement mortar is spread upon a course of well consolidated crushed stone upon which a second course of stone is placed and the whole thoroughly consolidated by rolling until the mortar flushes to the surface. Author concludes that mortar macadam, although low in first cost, does not form a durable pavement, it being usually necessary to surface treat within one or two years. Construction by this method has therefore been largely abandoned in Belgium.—F. H. JACKSON

Results obtained by use of cement in Denmark. S. ELLERT, E. SUENSON AND P. ORUM. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Report describes a number of experiments in use of cement in road construction since 1924, including construction of a concrete pavement in accordance with methods used in U. S. as well as several sections of so-

called mortar macadam. Results of the trial section of concrete have been excellent. The cost of this type is so high, however, as to prevent its adoption in place of Durax (stone block) with which it has to compete. Various trial sections with cement macadam have been built. The methods include the use of both a dry cement-sand mixture and a cement grout with which to fill the voids in broken stone course. Use of dry mortars was not satisfactory due to difficulty in filling the voids completely. The results with grout seem to be reasonably satisfactory and the cost is considerably less than ordinary concrete. Warning is sounded as to comparative load supporting capacity of cement-macadam road and concrete road. With increase in traffic by motor truck, the time is probably not far distant when intensity of such traffic will require construction of concrete pavements and it is intimated that immediate economy of using more temporary road surfaces will hardly be economical in the long run.—F. H. JACKSON

Results obtained by use of cement in Spain. JOSE RODRIGUEZ SPITERI AND FRANCISCO DE ALBACETE. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Results which have been secured on a number of short sections of concrete pavement constructed in various parts of Spain are reported. A typical pavement on highway from Madrid to France through La Junquera has the following characteristics: Width, 23 ft.; thickness, 9 in. Proportions: cement, 760 lb.; sand, 16½ cu. ft.; gravel, 29 cu. ft.; water, 4.2 to 5 gal. per 7 cu. ft. of concrete. Expansion joints were 48 to 64 ft. apart, and the pavement was cured by ponding, except a small stretch cured with Hunt process. This pavement was constructed in 1928 and is giving satisfactory service. More cracks are reported in section cured by the Hunt process than in the water cured section. Report also describes so-called mosaic concrete pavements as constructed in Spain. These roads consist of a concrete base, 6 in. thick, a cement mortar course 2½ in. thick and a top course of small stones with portland cement mortar binder. The diameter of the stones in the surface course varies from 3 to 5 in. on upper side and height is from 5 to 3½ in. The bottom area is 75 per cent of the surface area. These pavements are in reality stone block wearing surfaces embedded in a cement mortar cushion and laid on a concrete base. They appear to be giving excellent service under traffic carrying a substantial portion of steel tired horse drawn carts.—F. H. JACKSON

Results obtained by use of cement in France. R. BOUTTEVILLE. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Development of cement concrete road has been retarded in France by reason of high cost. At end of 1928, approximately 605,000 sq. yds. of the highway system had been surfaced, out of a total area of 1,030,000 sq. yds., including city streets. Indications are, however, that the amount of paving of this type will rapidly increase within the near future. As the result of test and experiment since the war, the methods of construction have become fairly well standardized. The report covers the various details of design and constructon as now practiced in considerable detail of which the following is a brief summary: Concrete pavements are either laid upon old stone road, reshaped or upon a foundation of stone or ordinary concrete. Thickness of slab varies, depending upon conditions, from 4 to 8 in., with a tendency to use the thicker sections. Pavements are in general of uniform depth, although an increased edge thickness of from 2 to 4 in. is sometimes used. Longitudinal joints are only used in pavements over 25 ft wide. Transverse joints are placed from 32 to 130 ft. apart with a tendency to the shorter lengths. Although recognizing the advantages of laying slabs in alternate sections from the standpoint of crack width, the practice has not been followed in France due to construction difficulties. The use of reinforcement is exceptional; only being used to increase resistance to bending on very unstable ground. Tests having shown that resistance to wear

can be greatly increased by increasing the amount of cement and also by careful selection of aggregate the old practice of one course construction has been abandoned and a two course type adopted with a proportion of approximately 550 lb. of cement to 17½ cu. ft. of sand and 35 cu. ft. of stone for the lower course as compared to a mix having 1200 lb. of cement (usually super-portland) to 10½ cu. ft. of sand passing a ¼-in. sieve and 35 cu. ft. of hard crushed porphyry, diorite, etc. Considerable attention is paid to the grading of the aggregates. Concrete is mixed in central mixing plants and transported to the road in small carts or wheelbarrows. About 40 gal. of water to 35 cu. ft. of concrete is used. The concrete is compacted by pneumatic or vibrating hammers or plates several types of which are described. The consolidated concrete is finished by means of a longitudinal roller weighing 1100 lb., about 18 ft. long and 10 in. in diameter. The methods of compaction described have resulted in much denser and stronger concrete with a perfect bond between the courses. The report estimates the life of concrete roads as now constructed to from 10 to 15 years. Attention is called to the fact that some of older roads are now in need of surfacing and describes a pneumatic device for scarifying worn concrete surfaces. The author does not believe that concrete roads should be built unless they can be constructed to resist surface wear. Need of more detailed specifications for concrete pavement work is discussed.—F. H. JACKSON

Results obtained by use of cement in England. J. B. L. MEEK, D. A. DONALD, S. H. MORGAN AND R. A. B. SMITH. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Report discusses the theory of designing concrete pavements as well as the materials used and construction methods followed in England at present time. Effects of temperature, moisture and traffic upon design are discussed and necessity of artificial drainage in order to lower moisture content of subsoil is stressed. The theory of loads is discussed to some extent, attention being called to the fact that loads as high as 30 tons per axle have to be provided for. Widening pavement 18 in. or 2 ft. beyond actual wheel path is practiced rather than thickened edge as used in the United States. Reinforcing is used on unstable soils, design varying with type and character of traffic. Slabs are usually reinforced both top and bottom. A minimum thickness of 8 in. is indicated for all main roads. Construction of slabs in longitudinal strips about 10 ft. wide is recommended with corresponding transverse joints 20 to 30 ft. apart in mass concrete and from 50 to 60 ft. apart in reinforced concrete. The alternate bay method is sometimes used, especially where it is desired to pave entire width at one operation and tampers and finishing boards cannot be used transversely. Due to necessity of providing a wearing surface of high resistance, pavements are usually constructed in two courses, using local materials in the base and crushed granite in the wearing course. The difficulty of applying a bituminous carpet which will adhere is discussed. The desirability of providing a carpet coat to take wear is noted however, and attention is called to the fact that application of a prime coat of tar or creosote will assist the carpet to adhere. Construction methods follow in general those used on the Continent. A dry mix is employed which is consolidated by tamping and cured by means of a 2-in. layer of sand kept wet. High early strength cements as well as, in certain cases alumina cements are employed when it is desired to open the pavement to traffic at an early age. The present day cost of concrete pavement in England varies from 8s to 10s per sq. yd., unreinforced but including excavating, etc. A method of constructing concrete roads known as the "sandwich" system is described. This consists in laying a course of broken stone, covering this with a plastic 1 to 2 mortar over which is spread another course of broken stone and the whole rolled with an 8-ton roller until the mortar flushes to the surface. This method has progressed well beyond the experimental stage and may be considered satisfactory. The cost varies from 5s to 7s per sq. yd. for a 4½ in. depth.—F. H. JACKSON

Results obtained by use of cement in Italy. L. DELL GUADIO, F. COLAMONICO AND I. VANDONE. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Use of concrete as a paving material in Italy dates back about 18 years. Concrete roads of the Soliditit type now comprise about 218,000 sq. yds. A notable development has been the use of concrete on the roads which are built to carry automobile traffic exclusively. A total of 1,570,000 sq. yds. have so far been constructed with about 1,210,000 sq. yds. to be laid in the near future. Concrete in "motor roads" is proportioned, mixed and placed in accordance with American practice. No steel tired traffic is, however allowed on these roads. For the main roads it has been found necessary to adhere to the European practice of two course construction, using a dry mix which can be tamped into place and hard wear resisting aggregates. A major portion of the report is devoted to a description of an experimental road constructed in 1929 which was built for purpose, primarily of developing means for constructing one half of the total width at a time so as to leave other half open for traffic. Other variables studied included the construction of alternate sections; proportioning by weight instead of by volume; using different grades of coarse aggregate; using 5 different cements; using various proportions of cement from 660 to 990 lb. per cu. yd., using various consistencies, using various consolidating and finishing methods, using single course as compared to two course work and using various thicknesses of slab. The above form 108 different combinations, each section being 15 ft. long and 11½ ft. wide. In order to accelerate the results of this test, an artificial steel tired traffic of 180,000 tons was carried over it. This did not produce enough wear to permit of a satisfactory comparison, which is now being obtained by means of very accurate level readings on plugs set in the pavement. These tests are being supplemented by profilometer tests to determine surface irregularities, in much the same way as is done in the United States. The results of this experiment are being awaited with great interest by the authorities.—F. H. JACKSON

Results obtained by use of cement in Holland. P. W. SCHARROO AND J. W. CLERY. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—This report, after calling attention to the inherent advantages of concrete as a paving material, calls attention to the fact that good results can only be secured when great care is used in construction. Only specialists and contractors who can provide proper personnel and good materials should be employed. Open bidding for this reason is out of the question. Concrete paving in Holland is still in beginning of its development. Unstable soils present great difficulties to this as well as other types of construction. During years 1925 to 1929 about 47 miles of concrete had been laid on the national system of roads as well as a small amount in the cities. The theoretical discussion of factors which affect density of concrete, importance of avoiding oversanded mixes is stressed as is also the necessity of using hard, strong and clean well graded aggregates. Use of dry mixes which have to be tamped is advocated in order to increase density. Ordinary portland cement will give as good results as super-cement. Although practically all roads in Holland are built in two courses, authors favor one course construction, on account of difficulty of properly bonding two courses together. Resistance to wear is of great importance and increases with strength and density. Water content should be kept low. Bituminous carpet coats have not proved satisfactory. Water glass is used as a surface treatment to increase hardness. Authors doubt the value of the treatment in case of concrete of proper density. Practically no reinforcement was used until 1928. Experiments, however, with longitudinal bars have indicated value of reinforcing of this type. Most recent practice as to joint construction has been to follow American practice, with tongue and groove longitudinal joint and transverse joints supported at ends with dowels fixed in one slab, but free to move in the other. Authors however,

are not entirely satisfied with this method, believing that joints should be so constructed as to leave slabs entirely free to move with respect to each other. They doubt that this is the case in American practice. Conclusion is drawn that concrete roads if properly built are better adapted to intense traffic of heavy vehicles than any other type.—F. H. JACKSON

Results obtained by use of cement in Sweden. E. PAUL WRETLIND. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Modern cement concrete roads now extend all over south portion of Sweden. During period 1925 to 1929 a total of approximately 15 miles was constructed, all single course construction. In 1926, a special specification covering a high grade portland cement was introduced. This cement known as Class A is used in public road construction. The requirements for strength at 7 days are almost double that of ordinary portland cement. Report describes an experiment with the alternate bay type of construction, in which openings 1.6 ft. wide were left at end of each 100-ft. slab and these openings filled with reinforced concrete about three weeks after the construction of the long slabs. In order to preserve alignment the reinforcing was doweled into the ends of the long slabs, with proper provision for slippage. Curing is done with wet sand, earth and straw. Sodium Silicate is used as a surface hardener without, however, any appreciable benefits.—F. H. JACKSON

Results obtained by use of cement in Switzerland. E. WYDLER. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—Very few concrete roads were built in Switzerland before 1929, due, first, to high cost and, second, to fact that political sub-divisions of country into 25 Cantons is not favorable to establishment of a unified system of roads. Approximately 105,000 sq. yd. of concrete was laid in 7 Cantons in 1929. General practice is to lay concrete on old well compacted stone bases. First pavements were constructed in two courses, using a rich mix and very hard aggregate in the top course to minimize surface wear. Results are not satisfactory due to excessive cracking of the top course. Present practice is to use either one course or two courses, using same proportion in each. In accordance with continental practice, a very dry mixture is used which is either tamped in place with pneumatic tampers or finished with a finishing machine. It is concluded that longitudinal joints should not be used when width is less than 20 ft. Transverse joints should be constructed about 33 ft. apart. Trouble has been experienced with joints due to abrasion and impact. It is concluded that joints should be filled absolutely flush with the road surface with an unyielding material.—F. H. JACKSON

Results obtained by use of cement in the United States. FRANK T. SHEETS, ROY W. CRUM, E. M. FLEMING, A. N. JOHNSON, CLIFFORD OLDER AND R. E. TOMS. *Proc. 6th Congress*, Perm. Internat. Assoc. of Road Congresses, 1930.—At end of 1928 there had been constructed in the United States on strictly rural highways approximately 59,000 miles of portland cement concrete pavement, or more than four times mileage which existed at end of 1920. During year 1928 alone, 8,756 miles were built. Such intensive construction has necessarily called for the rapid development of design and construction practices. This report outlines the present methods employed in design, construction, and maintenance of concrete pavements. Considerable advance has been made in structural design of pavements. Report calls attention to certain fundamentals which should be observed in construction of subgrade, and reference is made to new developments in design of cross section, as well as important features in proportioning of reinforcing steel and construction of expansion joints. The trend is towards intensive research as to effect of various characteristics of constituent materials on quality of concrete. Recent investigations indicate that characteristics of the aggregates have more influence on tensile and flexural strength of concrete than upon compressive strength.

The design of concrete mixtures by the water-cement ratio and mortar-void methods is rapidly gaining in favor. To secure benefits of proper design of mixtures, the ingredients must be accurately measured and water content closely controlled. These important features are described and references given to more complete information. Rapid strides have been made in development of equipment for handling materials and for mixing and placing concrete. Rigid inspection and modern equipment have aided in securing improved quality, smoother surfaces, and better production. The curing problem still needs much study. The rapidly increasing mileage of concrete pavement has stressed the problem of maintenance. Much study has been given organization, methods and equipment. Some of more important methods are described. One new development is the use of high early strength concrete for repair work.—F. H. JACKSON

Final conclusions reached by Permanent International Association of Road Congresses. *Proc. 6th Congress*, Washington, D. C., 1930.—(1) Cement is becoming generally used as a paving material and has many inherent advantages. Rapid hardening cements have special advantages in particular circumstances. (2) Cement has been used successfully in construction of cement concrete base courses for other surfaces, for cement concrete pavements, and for cement-bound macadam. (3) Cement concrete pavements and also cement concrete base courses protected by appropriate wearing surfaces are suited to heavy traffic. (4) Where a large volume of steel-tired traffic is encountered, if cement concrete is adopted as a pavement material, a two-course pavement with the upper layer composed of very hard aggregates should be used instead of a single-course pavement. (5) Single-course pavements have successfully carried maximum volumes of traffic and maximum wheel loads when the traffic was largely rubber tired. (6) Cement-bound macadam has been successful on roads carrying light traffic not inimical to the macadam type of construction. This method seems especially advantageous in locations where the conditions of drainage or exposure are unfavorable to the use of ordinary waterbound macadam. A protective wearing surface seems equally indispensable on cement-bound and water-bound macadam. (7) In designing cement concrete pavements and cement concrete base courses to be surfaced with other materials the resulting pavement should have equal load-carrying capacity or structural strength, when similar traffic conditions are to be met. (8) Competent engineering supervision of design, construction, and maintenance of cement concrete pavements is necessary to insure good results. (9) It is desirable that subgrades be uniform and stable. (10) Pavement slabs must be designed to carry expected loads. Edge thickening is advantageous as a means of producing an economic and balanced structural design for concrete pavement slabs. (11) Longitudinal and transverse joints are commonly used and must be designed to meet traffic, subgrade, climatic conditions, and shrinkage of concrete, but in view of the fact that a number of concrete roads have been successfully constructed without joints, it is advisable that further research should be made on the whole subject of joints and cracks. (12) Scientific design of concrete mixes and weight proportioning of aggregates represent the most modern practice. (13) Construction operations are performed mostly by machinery, with resulting lower cost and better workmanship. Value of a cement concrete roadway depends to a large extent on perfect execution of work and, in particular, on homogeneity of the concrete. (14) Thorough curing of concrete surfaces is essential. (15) Maintenance of concrete surfaces, properly constructed, is relatively simple and reasonable in cost. In particular, maintenance should comprise immediate filling with suitable material of expansion joints and of any cracks which may occur.—F. H. JACKSON

The experimental street of Binasco. ITALO VANDONE. *L'Industria Italiana Del Cemento* (Italy), Feb. 1930, p. 8-15.—An experimental section of

concrete road was constructed along Pavese St. in Binasco in connection with the study of the problem of developing a type of paving that could be placed over the existing substructure and which would economically resist the action of both automobiles and horse drawn traffic. About 180 sections 11.5 ft. wide and 14.8 ft. long covering 108 different conditions were poured. The variables included 5 different crushed stones, one gravel, 5 different cements, 4 proportions of cement, 2 to 6 different consistencies, 2 depths of paving and two types of paving (single and double layer). Concrete was placed in half road width sections, the other half of road remaining open to traffic. Concrete was mixed at a central point and conveyed to place by a narrow gauge railway. Very careful attention was given to control of various quantities entering into the mix. The sand and gravel were weighed. Gravel was separated into sizes to promote uniformity. Difficulty was encountered in controlling the water content with the usual water tank on the mixer. Samples of concrete were taken at time of pouring for laboratory test but it was considered that complex disintergrating action of the steel wheel animal drawn traffic could be only properly shown by a large scale test under real traffic. Numerous horse drawn wagons were therefore circulated over the experimental section for several days. The wear was concentrated in a narrow lane so that a condition equivalent to one year of normal traffic was simulated. Very little wear resulted except for the removal of the surface skin. Measurements of profile of pavement were taken by a special apparatus which makes a continuous record as the machine moves along. It is planned to repeat measurement at intervals to learn something about the way in which deterioration of pavement occurs. Economics of use of concrete roads in Italy is discussed and it is concluded that this type of road can be properly used when it costs no more than other types when all factors of cost including deterioration and maintenance are considered.—C. G. CLAIR AND M. N. CLAIR

WATER WORKS

Water tower in Hassloch i. Palatinate (Germany). *Zement* (Germany), Oct. 16, 1930, V. 19, No. 42, p. 999.—Foundation of structure consists of one circular reinforced concrete slab, 34.4 ft. in diameter, heavily reinforced radially and circumferentially. Cylindrical stair case (4.9 ft. in diameter), in which pipe lines for feed and discharge are located, is erected in center of foundation slab. Tank consists of two concentric containers, each of which has capacity of 132,000 gallons. Outer diameter of tank is 52.5 ft., its height is 24.6 ft. and depth of water is 23 ft. It is carried on a circle of 12 reinforced concrete columns connected by two horizontal concrete rings each placed at one third of total height of columns. Tank is faced outside with hollow cast concrete bricks to protect structure against temperature effects. Ceiling is 4.7 in. concrete slab. Total height of structure is 144.4 ft.; 390 tons cement, 1265 tons sand and gravel and 126 tons steel were used for its construction.—A. E. BEITLICH

SHOP MANUFACTURE

Achieving light-weight building unit with ordinary aggregate. D. R. COLLINS. *Concrete*, Nov., 1930, V. 37, No. 5, p. 20-22.—The standard size 12-in. product of block manufacturer at Cedar Grove, Wis., weights 7 lbs. less than the 8 by 10 by 16 in. unit he manufactured a year ago. Corresponding saving in weight has been made in the 10-in. unit. Saving is due to substitution of rectangular for oval cores—taking material out of the corners and thinning the webs. The manufacturer is making units 7¾ in. high by 15¾ in. long. His average 8 in., 10 in. and 12 in. units weigh from 42 to 44 lb., from 51 to 53 lb., and from 60 to 62 lb. respectively. When a thin-webbed unit is being made it

requires careful supervision of the mix and the manufacturing operation, and should be handled only in a high-grade plant having a reputation for high-grade products.—C. BACHMANN

Proposed German standard specifications for light cast stones made from pumice. *Zement* (Germany), Sept. 11, 1930, V. 19, No. 37, p. 879-80.—Three different types are specified: stones made from pumice aggregates with (1) hydraulic or dolomitic lime, (2) cement and other hydraulic binders and (3) with only or mostly cement or special cements. Form of units must be 10 in. long, 4.7 to 6.3 in. wide and from 2.5 to 5.5 in. high. Compressive strength must be for units made with lime, 170 lb. per sq. in.; with cement, 284 lb. per sq. in. and with special binders 427 lb. per sq. in. Average of 10 tests must be determined. Weight per cu. ft. should not be higher than 52.95 lb. Heat conductivity number for air dried units should range from 0.13 to 0.16 at 68° F. Units must stand freezing and thawing 25 times. Additional data are furnished explaining origin and geologic nature of raw material, chemical composition, porosity, physical structure and possibilities for application in construction practice.—A. E. BEITLICH

What is a fair market price for light-weight units? H. H. POTTS, *Concrete Products*, Oct., 1930, V. 39, No. 4, p. 16-17.—The material considered is a concrete unit for backing and partitions, and may be of any of light-weight aggregates now on the market. Their value is considered in relation to clay tile and complete data worked out shows what the cost of concrete units would be to compete with clay units at various market prices: for example if 5 by 8 by 12 in. clay tile are delivered to the building site at a price of $65.00 a 1,000, then 8 by 8 by 16 in. light-weight concrete units are worth $170.00 a 1,000 delivered. The author then works the problem still further to show that light-weight units of this size can be sold at a price of $170.00 per 1,000 or 17¢ each and carry a profit of 2¢ each.—E. S. HANSON

Two-in-one concrete pipe plant at Beloit, Wis. *Concrete Products*, Oct., 1930, V. 39, No. 4, p. 12-15.—The plant of the Illinois-Wisconsin Concrete Pipe and Tile Co. at Beloit, Wis., occupies the site of a worked out sand and gravel plant and is separated into two departments, one for making pipe up to 24 in. in diameter of the bell and spigot type and the other for making pipe from 21 up to 60 in. of the bevel joint type. Plant also manufactures larger sizes by hand. Handling of products has been worked out very efficiently by means of two travelling cranes and several small tractors with trailers, also tractors with caterpillar tread for pulling and pushing larger sections.—E. S. HANSON

Random ashlar walls. W. D. M. ALLAN, *Concrete Products*, Oct., 1930, V. 39, No. 4, p. 34-36.—This concluding article of a series of three on concrete random ashlar describes the manufacture of the various concrete masonry units required for typical random ashlar wall construction. Almost any plant equipped to manufacture standard concrete masonry units usually can, with only a few changes in existing equipment, manufacture units which can be used in building random ashlar walls. For typical wall construction, seven sizes of units, in which the dimensions of the exposed faces determine the sizes, will permit the flexibility ordinarily required in designing random ashlar patterns. Inasmuch as concrete random ashlar walls usually are built as 4-in. veneers or 8 in. masonry walls, this discussion deals with manufacture of units 4 and 8 in. thick. However, the operations are practically identical for producing units having other wall thicknesses.—E. S. HANSON

Materials

Admixtures

Densifying of mortar and concrete against dampness and water under hydrostatic pressure. Hugo Leube. *Betonwerk* (Germany), May 18, 1930, V. 18, No. 28.—The use of densifying admixtures discussed. Admixtures for this purpose are divided into three classes, namely: liquid, paste and powder. Each is analyzed as to proper mixing technique.—H. Frauenfelder

Aggregates

An accelerated soundness test. Dr. Herbert F. Kriege. *Civil Eng.*, Nov., 1930, V. 1, No. 2, p. 120.—Detailed consideration is given to sodium sulfate soundness test as applied to concrete aggregate (fine and coarse), filter bed sands, and coarser mineral aggregates commonly employed as sewage disposal media. Although this test dates back to 1828, it has not been fully or uniformly controlled. The essential elements in the test are outlined and explained and detailed procedure is suggested. Of thirteen cooperating laboratories, the eight laboratories that followed suggested procedure closely, correctly classified ten kinds of slag and stone into sound, unsound, and questionable groups. Much of suggested procedure represents a consensus of opinion from the answers to 99 questionnaires sent to prominent engineers in the fields of highway, sanitary and testing engineering.—H. J. Gilkey

Gasoline tractors and trailers in limestone mine. *Rock Products*, July 19, 1930, V. 33, No. 15, p. 64.—Centropolis Crusher Co., 8 miles from Kansas City, Mo., mines limestone by room and pillar method. Rooms are 30 ft. wide with 25-ft. pillars. The level is such there is no upgrade to the crusher. Air hammer drills put in 16 ft. holes which are loaded with 40 per cent powder. Top cut is taken and remaining bench is lifted. The working height is 16 ft. Loading is by 1-yd. shovel with 12-ft. boom and 7-ft., 8½-in. dipper stick. It is equipped with an electric light outfit including a 250-watt floodlight. Haulage is by two tractors and side-dump trailers. Distance from face to crusher is about 500 ft. Two trailers deliver 1,200 tons per 10-hr. day and gasoline consumption is about 80 gal. Between shifts tractors and trailers haul fines to dump. Direct charges for labor, fuel and oil approximate 3¢ per ton. The crushing plant, of conventional design, produces these sizes: 2-in., 1¼-in., ¾-in., ½-in., buckshot and fines. The output is sold in considerable part to make ready mixed concrete.—Edmund Shaw

Influence of dust content in aggregates on weight per cu. ft. and compressive strength of concrete. G. Kathrein. *Oesterreichische Bauzeitung* (Austria), Oct. 25, 1930, V. 6, No. 43, p. 705-7.—Additions of limestone powder of different finenesses were made to aggregates, and their influence on mortar and concrete properties examined. High early strength cement was used for preparation of 2¾-in. cubes of 1:5 cement : sand mixture with additions of 4, 10 and 20 per cent limestone powder of 2 different finenesses. Compressive strength and weight per cu. ft. were determined after 7 days air storage. It was found, that additions of stone powder have favorable influence on mortar strength, which increases about 50 to 85 per cent with additions of 4 and 10 per cent. Addition of 20 per cent lowers strength. Fine powder has greater influence than coarse particles. Weight per cu. ft. shows similar behavior, increasing with 4 and 10 per cent and decreasing with 20 per cent additions of stone powder.—A. E. Beitlich

Standardization vs. discrimination. Stanley Hands. *Rock Products*, Sept. 27, 1930, V. 33, No. 20, p. 46-48.—The practice of proportioning concrete

by a definite grouping of a limited range of sizes of aggregates appeals to the engineer because it relieves him of much detail and he is not concerned with losses of production. Fact that other methods of proportioning would produce concrete of same quality is not important to him. If, however, he has to produce his own aggregate he will adopt methods of proportioning not based on accepted standards but on natural laws covering use of aggregates as he may find that his pet proportions create undue waste. Discrimination in this case will be favorable to more use of run-of-the-pit. Standards may change but fundamentals and natural laws do not change. The application of fundamentals may make it undesirable that some things should be standardized. Some concrete workers think that the art is working toward discrimination in use of materials. Most of fundamentals are ready. Only cooperation of producer is needed. Utility of aggregates is not to be considered from standpoint of *what* they will make alone but *how* they will make what is intended. Measure of their utility lies in profitableness of their use. The surface property of an aggregate may be an important factor. It is generally known that some surfaces become covered with a gelatinous film that is often transparent and not easily detected. Material which may qualify under grading and sizing standards may be found undesirable for lack of bonding quality. Research has not determined all conditions and proportions that make differences in materials. Until adequate facts are known it would be undesirable for the industry to set up standards. All aggregate associations have exceptional research organizations and it is very desirable that their work be continued.—EDMUND SHAW

Effect of flat and elongated particles in mineral aggregates. STANTON WALKER. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—The purpose of the report is to cite whatever of definite information is available on the effect of flat and elongated particles and to suggest procedure for investigations. Although specifications have commonly drawn discriminatory lines against such material, there are little data upon which to base definite requirements. Research conducted by the National Crushed Stone Association and the National Sand and Gravel Association indicate that flat and elongated particles in the amounts to be expected in practice (10 to 15 per cent) do not have deleterious effects upon workability, strength, finish and quality of surface of concrete. Some tests reported by Gilkey on specially prepared aggregates where the coarse aggregate consisted entirely of flat particles indicated some weakness. It is concluded that further investigations are required before generally acceptable conclusions can be drawn and suggestions for procedure are made.—HIGHWAY RESEARCH BOARD

Uniform description of graded materials and evaluation of their fineness. M. SPINDEL. *Tonind. Ztg.* (Germany), Nov. 2, 1930, V. 54, No. 88, p. 1385-6; No. 89, p. 1401-3.—Surface areas of aggregates are constant for any given fineness modulus so that any change therein gives a direct measure of work performed during grinding. A metric fineness modulus is proposed with the sieve openings $10°$, 10^1, 10^2 . . . 10^5 microns as basis with each range divided into five fractions with intermediate sieves the log. of whose openings shall be 1.0, 1.2, 1.4, 1.6 . . . 5.0, which then correspond to the fineness moduli of gradings of broken solids whose mean sizes correspond to the several sieve openings. This system has the advantage of being applicable to cement and other fine materials.—F. O. ANDEREGG

Bethlehem Mines' newest crushed stone plant. *Rock Products*, Aug. 2, 1930, V. 33, No. 16, p. 33.—At the Steelton plant of the Bethlehem Mines Corp., which produces concrete aggregate, flux and furnace lining dolomite, the sizes of stone to be sold as aggregate are thoroughly washed. Scrubber is 6 ft. dia. and 20 ft. long and capacity of washing plant exceeds 200 tons per hour. The rotary screen has a 6-in. pipe with 52 $\frac{5}{8}$-in. holes for washing the material

received from the scrubber. Additional sprays play on the outside of the screen. Only fresh water is used in the screen and after use there it is sent to the scrubber. The plant is all steel and concrete construction.—EDMUND SHAW

Crushed stone producer noted for originality builds sand plant. *Rock Products*, Oct. 11, 1930, V. 33, No. 21, p. 41-45.—Sand and gravel plant of Dolomite Products Co., Rochester, N. Y., owned and operated by John Odenbach employs an unusual method of handling with a much simplified washing and screening plant. The material is excavated by a 12-in. centrifugal pump on a steel dredge. It is boosted to help it through a 600-ft. pipe line by a 10-in. pump in a permanent concrete building. The full lift is 138 ft. The screening plant has a double-deck vibrating screen below a steel sluice box for the first separations, 2½-in. square meshes on the upper deck and $\frac{3}{16}$-in. square meshes below. Oversize goes to a No. 5 crusher with no return to the screen. The intermediate product goes to a 3-deck vibrating screen to be finished. It has 2¼-in., 1¼-in. and ½-in. meshes and all products go to pockets. The minus $\frac{3}{16}$ in. from the primary screen goes to automatic sand cones. The pockets for holding material are of concrete set below the ground level. They are discharged by a high speed travelling crane with 2½-yd. clamshell bucket, the runway being 40 ft. above rails. Bucket discharges into ten 65-ton steel bins for truck loading or into 3 compartment, 150-ton batching bins. Only steel and concrete are used in construction.—EDMUND SHAW

Light concrete for construction of 400 dwelling houses in Berlin-Zehlendorf. (See FIELD CONSTRUCTION—BUILDINGS.)

Reinforced concrete construction. Part I. Raw materials and their production. (See FIELD CONSTRUCTION.)

Relation between durability of concrete and durability of aggregates. (See PROPERTIES OF CONCRETE.)

CEMENT

Discussion on "A tentative specification for high alumina cements." *Structural Eng.* (England), Nov., 1930, V. 8, No. 11, p. 380-384.—The tentative specification which appeared in Oct. 1930, issue of Structural Engineer is discussed in considerable detail.—V. P. JENSEN

Portuguese standard specifications for cement. *Tonind. Ztg.* (Germany), Oct. 16, 1930, V. 54, No. 83, p. 1319.—Cements of "lower strength" must have at least 2850 and 243 lb. per sq. in. after 7 days water storage and 4300 and 300, compressive and tensile respectively, after 28 days in water. Cements intended for use in sea water must meet the above requirements when stored in sea water and must have at least 5000 and 330 lb. per sq. in. after 84 days similar storage.—F. O. ANDEREGG

Ashes absorbed by cement clinker. H. MOSCHITZ. *Tonind. Ztg.* (Germany), Nov. 13, 1930, V. 54, No. 91, p. 1430-1.—Dust removed from a cement kiln working with thickened slurry was about 3 per cent, most of which escaped from the stack. The clinker takes up about 40 per cent of ash.—F. O. ANDEREGG

Soluble salts in portland cement. *Betonwerk* (Germany), April 13, 1930, V. 18, No. 22.—The efflorescence sometimes noted on concrete and cast stone is discussed and its formation described. Cause is given as water soluble salts in cement. Method of determining these salts in cement is given and a suggestion for preventing efflorescence by use of barium oxide, which transforms soluble salts into insoluble.—H. FRAUENFELDER

German standard specifications for portland cement, iron portland cement and blast furnace cement. *Tonind. Ztg.* (Germany), Oct. 9,

1930, V. 54, No. 81, p. 1292-6.—These 3 cements are placed on a par, definitions being given for each. The composition of slag from which the two latter are ground with portland cement clinker is defined: $\frac{CaO + MgO + 1/3\,Al_2O_3}{SiO_2 + 2/3\,Al_2O_3} > 1$

Fineness is 2 per cent on No. 30 (75 mesh per in.) and 25 per cent of No. 70 (176 mesh per in.). The initial set shall be not less than one hour. The strengths 1:3 with German normal sand and with 8 per cent water must be at least:

Lb. Per Sq. In.

	Standard Cement		High Early Strength Cement	
Storage	Tensile	Compressive	Tensile	Compressive
3 days in water	...	....	357	3570
7 days in water	257	2570	...	....
28 days in water	...	3930	...	....
28 days combined	430	5000	570	7150

The tensile test is not regarded as of as much value as the other. Full directions are given for methods of testing.—F. O. ANDEREGG

Perchloride acid method of silica analysis—Its advantages over double evaporation. WALLACE K. GIBSON. *Rock Products*, July 19, 1930, V. 33, No. 15, p. 70.—The perchloric acid method takes only 30 to 45 m., according to the water that has been added to the solution, saving much of time that has to be spent on double evaporation of silica and further baking of dry residues. Care must be taken not to boil with ordinary dilutions as an explosion will occur before the boiling temperature is reached. If it is desired to boil, the solution should be about 150 cc. with a 0.5 g. sample. The article gives the perchloric acid method in detail with figures showing the silica contents found by this and other methods.—EDMUND SHAW

Improved grinding methods at the Diamond Portland Cement Co. *Rock Products*, July 19, 1930, V. 33, No. 15, p. 51.—At the Diamond Cement Co.'s plant at Middlebranch, Ohio, three 7 x 24-ft. compeb mills were formerly used in grinding raw material. One of these was put in closed circuit with a 14-ft. Sturtevant air separator and after a year's trial of this combination a second mill was similarly equipped. These two mills were then able to grind all the raw material needed. Without air separators each mill produced from 17 to 18 tons per hour. With air separators each produced 22 to 23 tons per hour. Material going to the separator from the compeb has 52 per cent minus 200 and 73 per cent minus 100. The finished product removed by the separator has 88 per cent to 89 per cent minus 200 and 97 per cent minus 100. Returns to the mill from the separator have 15 per cent to 16 per cent minus 200 and 46 per cent minus 100. Total circulating load is 46 tons per hour. Each separator takes 35 h. p. to drive. They are fed by steel encased elevators and the rejects are returned to the mill mixed with the primary feed.—EDMUND SHAW

Further developments in the application of dry fine grinding with air classification. HOWARD G. WRIGHT. *Rock Products*, July 19, 1930, V. 33, No. 15, p. 57.—It has been ascertained that it is more important in preparing material for cement manufacture to eliminate coarse oversize than to produce much "flour." Air classification with grinding is shown to give excellent results in holding the particle sizes within narrow limits. Separation made by reversed current system of air classification used with Hardinge mills is in three stages. Air blown into the mill through a trunnion is reversed and drops the coarsest particles in the mill. The same air issuing from the mill passes through a rotary separator where the medium-coarse particles are removed. Then it passes to a "superfine" air classifier which takes out all but the product desired, this being caught in a cyclone. Oversize particles from rotary and from "superfine" classifiers falls into air tube through which air is blown into mill

and are thus returned to the mill. Records show that power consumption is not much if any greater with air separation than without, added output of the mill making up for the power used by the classifier. A lower ball consumption has been noted. A feed of uniform quality is necessary for best results and installation of a constant weight feeder in one case gave 2.5 tons per hour added mill product.—EDMUND SHAW

Tentative specification for high alumina cements. Prepared by the Institution of Structural Engineers. *Structural Eng.* (England), Oct., 1930, V. 8, No. 10, p. 369-373.—Specification includes method of manufacture and composition of the cement, samples for testing, tests of fineness, chemical composition, compressive strength, setting time, and soundness. Sections deal with non-compliance of tests, copies of vendor's tests and analyses, and the Appendix gives a tensile test for acceptance purposes only.—V. P. JENSEN

Weight of slurry. E. TAYLOR. *Rock Products*, Nov. 8, 1930, V. 33, No. 23, p. 64.—The author shows how he derives the following formula for the weight of one cubic foot of wet slurry: $W = \frac{6243\ s}{100 - a + sa}$ in which W is the weight in lb., s the specific gravity of the dry slurry and a the percentage of water in the slurry.—EDMUND SHAW

Free lime, constancy of volume and strength. Report of research laboratory of the Association of German Eisenportland Cement Companies, Duesseldorf (Germany). A. GUTTMANN. *Zement* (Germany), Nov. 13, 1930, V. 19, No. 46, p. 1078.—Based on own experiments, author agrees in general with findings of G. Haegermann (c. f. *Zement*, Oct. 16, 1930, V. 19, No. 42, p. 982-4) concerning relation between volume constancy and free lime content of portland cement clinker. Presence of free lime has tendency to lower strength of clinker which contains much tricalcium silicate, but is able to improve strength of clinker, which is rich in dicalcium silicate, in later ages.—A. E. BEITLICH

Overcoming heat losses in cement manufacture. GEOFFREY MARTIN. *Rock Products*, July 5, 1930, V. 33, No. 14, p. 42.—The author leads up to a discussion of his own design of a flotation kiln by describing the heat losses in a rotary kiln and comparing with a shaft kiln which is more economical of fuel. He emphasizes that as clinker cannot be made at a lower temperature than 1370°C. (2498°F.), the kiln gases must have a higher temperature to impart this heat. But too high temperature cause high radiation losses. With coal firing a gas temperature of 2600°F. may be obtained. Higher temperatures if they were possible would be more efficient. Costly failure of British experiments at Swanscombe was due to ignorance of these facts. Hot exit gases were introduced into the kiln in an effort to save heat but gas temperature was cooled below 2500°F. and no clinker was formed. The great loss of high grade heat is internal radiation. Various methods to prevent this loss have been suggested and most promising of these is a cloud of spray or dust formed of raw materials in either a wet or a dry condition. These experiments are still going on. Author's flotation kiln, an improvement on design of Sir Percy Girouard, employs dust cloud principle mentioned. The kiln is a cavity worked out of a limestone cliff and it is of such a shape that the gases will circulate vertically. Raw material dust is fed into downwardly flowing side of this circulation and carried to bottom where there is a zone of intense heat. Dust falls through this and becomes clinker. It is discharged by conveyor in tunnel below. Gases after dust has fallen from them rise on other side of cavity and flow across to pick up more dust and descend.—EDMUND SHAW

Contribution to the question of fine cement grinding. ERNST RISSEL. *Zement* (Germany), Nov. 13, 1930, V. 19, No. 46, p. 1079-80.—Two brands of cement were ground to different finenesses and effect of grinding was studied by measuring water permeability of 1:6 mortar test specimens and com-

pressive strength. One fact developed is that fine grinding affects water permeability to a far greater extent than it does compressive strength. Based on this evidence author points out that examination of water permeability must be considered of greater value than compressive strength tests for valuation of cement obtained by fine grinding. Further tests dealing with very fine cement fractions are under way.—A. E. BEITLICH

Influence of mixing water on mortar strength. E. PROBST AND K. E. DORSCH. *Zement* (Germany), Oct. 23, 1930, V. 19, No. 43, p. 1009-11.—Standard compression and tensile strength tests were made with one high early strength cement, two ordinary portland cements, one blast furnace slag cement and one high alumina cement. Mixing water was in one case ordinary service water and in another case distilled water. Samples mixed with distilled water showed higher compressive strength and lower tensile strength than samples mixed with service water. Variations are different for different kinds of cement. Standardization of mixing water for standard test methods is suggested. Investigation of influence of storage water on strength properties showed no difference for different types of water.—A. E. BEITLICH

Lime and magnesia determination in portland cement raw mix. G. W. JORDAN. *Rock Products*, Sept. 27, 1930, V. 33, No. 20, p. 62-63.—Objections to usual acid-alkali method are: Iceland spar used as standard may contain as much as 1½ per cent impurities; color change of phenolphthalein covers a pH range from 8.4 to 10.2; $Al(OH)_3$ is soluble in excess of NaOH and Mg $(OH)_2$ is hydrolized during the continuation of the titration for magnesia alone. These errors neutralize one another but it does not follow that the net result is correct. The author recommends using solutions exactly 2/5 N HCl and 1/5 N NaOH, standardizing on pure (Bureau of Standards) potassium-acid phthalate, as an alkametric standard, with phenolphthalein as an indicator. One gram of raw mix is dissolved in a 200 cc. graduated flask with 50 cc. of 2/5 N HCl, the flask attached to condenser and boiled. While still hot enough to exclude CO_2 excess acid is titrated with the 1/5 N NaOH, methyl red being used as indicator. 0.05 cc. is added to NaOH reading for difference in pH value of methyl red and phenolphthalein as indicators. Corrected reading is subtracted from 100 to give lime equivalents of lime and magnesium carbonates. The solution is then brought to a boil and 50 cc. of N/2 neutral sodium oxylate solution is added to precipitate lime. The whole is diluted to 200 cc. and filtered. 100 cc. of filtrate, which should be alkaline to methyl red but neutral to phenolphthalein is titrated with a dilute alcohol-glycerine solution of potassium palmitate which is just alkaline to phenolphthalein. Red end point with phenolphthalein shows when all magnesia is precipitated, 0.3 or 0.4 cc. being subtracted. This is amount necessary to give a red color with a blank solution just alkaline to methyl red. One cc. N/10 potassium palmitate equals 0.002 grams MgO. No more time is needed than for the ordinary method and author believes results will be much more accurate.—EDMUND SHAW

Researches on the rotary kiln in cement manufacture. Part IV. GEOFFREY MARTIN. *Rock Products*, Sept. 27, 1930, V. 33, No. 20, p. 53-55.—The author shows how he derives the following formula for kiln output, which he believes to be original, $M = 1.263 \frac{S}{V} d^2$ tons per hour, M being output, V the volume of exit gases per lb. of clinker made and S their terminal speed and d the diameter of the kiln. For good practice, M equals $0.1123d^2$ tons per hour. For unusually good practice M equals $0.153\ d^2$ tons per hour. These are with wet process kilns. With dry process kilns M should equal $0.1356\ d^2$. While the author was with the British Association of Portland Cement Manufacturers the work of a number of kilns was compared with what it should be by this formula. Improvements in practice were thus introduced that gave large

savings, in one case amounting to $75,000 a year. It appears from this formula that kiln production may be increased either by reducing the volume, V, of gas per lb. of clinker or by increasing its terminal speed, S. Hence reducing fuel consumption per lb. of clinker or reducing exit temperature will give a larger output. The author has patented the use of fans for increasing the terminal speed S of exit gases. Where it is desirable that the speed should be lower in certain parts of the kiln baffles are placed in these parts.—EDMUND SHAW

Researches on the rotary kiln in cement manufacture. Part V. GEOFFREY MARTIN. *Rock Products*, Oct. 11, 1930, V. 33, No. 21, p. 58-59.—To make clinker raw materials must be heated to 1371 C. To attain this temperature kiln walls must be heated to a higher temperature but not high enough to fuse brick work lining. Assuming that all heat necessary to make clinker passes through clinkering zone, then surface area of clinkering zone must radiate away absolutely as much heat as passes through the clinkering zone per unit of time. From the above, the formula for surface of kiln in clinkering zone is derived: $S = 315.7 \frac{M}{y}$ sq. ft. where M is the output in long tons of clinker per hour and y is pounds of clinker produced per pound of fuel. In an example y is assumed to be 3, corresponding to a fuel consumption of 33 per cent and required surface area works out to 105.2 M sq. ft. A table appended gives the surface areas of clinkering zones for outputs of 1 to 10 tons per hour. To find required length, L, of the clinkering zone: It has been shown that diameter of kiln, d, is $2.98\sqrt{M}$, and since $L = S/\pi d$, L works out to $11.24\sqrt{M}$. From these the size of the clinkering zone for any output of a rotary kiln may be calculated. A table is appended giving dimensions for outputs from 1 to 45 tons per hr. and for diameters from 3 ft. to 20 ft.—EDMUND SHAW

Constitution of cements. NORBERTO P. COSTA. *Doctoral Thesis*, National University of Buenos Aires (Argentina), 1930, 32 p.—Author presents a detailed microscopical study of three classes of cements. Clinkers or unpulverized cement were submitted to different methods of cooling after having been heated in an oven to 2597° F. for portland cement clinkers and to 2732° F. for aluminous cements. The methods of cooling were in the oven, in air, in sand, in oil, in water and in ice. Plates for examination were made by placing pieces of clinker into hot Canadian balsam. After cooling, these plates were ground and polished. Argentina portland cement obtained by dry process, one high early strength German portland cement obtained by wet process, and one French cement, high early strength, were used. Work is based on a study by Doctor Hendrick. Some of objects of thesis were to study the very great influence of large crystals in the clinker, its size, its grouping around a nucleus and its effect on the strength of cements. These characteristics were attributed to two fundamental operations in making a good cement, namely, heating and cooling. Conclusions by author are briefly: That a clinkerized cement is not simple mixture of aluminates and silicates, but it is very probable that, in its constitution, they form partly solid solutions of isomorphic mixtures of silicates of calcium and of iron, with aluminates of calcium. That the fused cements are formed by a mixture of aluminates, silicates and silica-aluminates of calcium, mixed with slag of silicates of iron. Aluminates seem to crystalize in the body of the slag, while silicates and silica-aluminates crystalize in the vitreous mass (vidrio) of their own composition. Predominant element in these cements is $5CaO, 3Al_2O_3$ in its unstable form. Portland cement obtained by wet process has same proportion of constituents as portland cement obtained by dry process, but in the first case most of the crystals of Alit and Celit are uniform and of somewhat larger size. Grouping of grains of Celit around a nucleus of Alit were observed. This was not observed in cements from the dry process. (Celit—solid solution of di-calcium aluminate in di-calcium silicate. Alit—solid solution of tri-calcium aluminate and tri-calcium silicate.) In

portland cement of high initial strength—obtained by the dry process—it is observed that proportion of Celit is greater than in other cements and grains of Celit and Alit are larger. Therefore, high strengths of a cement are a consequence of crystalline groupings, and of size of crystals, above all those of Alit. Most interesting form is grouping of crystals around a nucleus of other crystals, in a radiated spheroidal form. In portland cements, quenching, or cooling, causes a variation in some physical characteristics of crystals, but its chemical constitution remains constant. However, in fused cements, action of cooling changes chemical constitution. Many micro photographs and a two-page bibliography are included.—N. H. ROY

Investigations on protection of concrete against aggressive solutions. (See PROPERTIES OF CONCRETE.)

Austrian tests on concrete columns with high quality steel reinforcements. (See ENGINEERING DESIGN—MISCELLANEOUS.)

PROPERTIES OF CONCRETE

The analysis of the solid concrete body, a means for production of concrete mixtures of great value. ERICH WEISE. *Die Bautechnik* (Germany), May 2 and 16, 1930, V. 8, No. 19-21, p. 284-7, 315-8.—Cementing properties, voids, cement content, water-cement ratio and compressive strength of concrete mixtures were studied and subjected to mathematical calculations. It is pointed out, that excess of water must be avoided. Decisive for properties of finished concrete is water content, which fact is expressed by w/c-ratio. Amount of water which adheres to aggregates is of great importance. Above a certain limit, an excess of water will be of less influence, when used for cast concrete. A number of formulas for calculation of valuable concrete mixtures are derived.—A. E. BEITLICH

Research comes out of the attic. WYATT BRUMMITT. *Concrete*, Dec., 1930, V. 37, No. 6, p. 28-30.—Industry today has taken over duties of research with same motive as that of struggling scientist of last generation. Portland Cement Association laboratory at Chicago is typical of industrial research. Work was begun with no definite goal but recognition of need for larger knowledge of cement and concrete. One of first projects was establishment of suitable measuring stick to gauge phases of work. Strength assumed of vital importance and effort made to determine effect of cement content, quantity and proportion of aggregate, and mixing time. Water content considered secondary until experiments led to water-cement ratio law. Three classes of investigations now interest researchers: Continued analysis and refinement of cement-producing process; perfected technique of using concrete under "impossible" conditions; and widening range of uses. Department, headed by F. R. McMillan, occupies half of 5 story building, employs 50 men, and maintains fellowship for research at Washington. Findings of quarter-million experiments are on file.—C. BACHMANN

The question concerning the water impermeability of concrete. VOGELER. *Bautechnik* (Germany), May, 1930, V. 8, No. 23, p. 342-3.—Author discusses directions, which are given in book: Specifications for mortars and concrete (Anweisung fuer Moertel und Beton; cf. *Zement* (Germany), Jan., 1930, V. 19, No. 3, p. 64, *J. of the Amer. Concr. Inst.*, April, 1930, V. 1, No. 6, Abstr. Sect. p. 68) concerning relations between aggregate gradation, mixing water and water permeability of concrete. Ostendorf gives his experiences with the preparation of concrete of high water impermeability and outlines further investigations in this line.—A. E. BEITLICH

Collapse of a lock in Huentel (Germany), investigation and repairs. RUDOLF JEHN. *Bautechnik* (Germany), June 27 and July 18, 1930, V. 8, No. 28-31, p. 438-41, 478-81.—Investigation of concrete and local conditions revealed that sewer water and ground water contained only small amounts of harmful sulphates and magnesium salts but very great amounts of aggressive carbon dioxide, which fact, together with porosity of concrete led to its destruction. Bottom slab of concrete showed stratification and layers of sound and disintegrated concrete. Repairs of lock consisted of removal of old concrete bottom and replacement by new slab. Concrete with an addition of trass was used and was worked to a very dense structure. It was provided with heavy reinforcements.—A. E. BEITLICH

Analysis of complicated concrete mixes. J. L. HEINTZMAN. *Rock Products*, Nov. 8, 1930, V. 33, No. 23, p. 62-64.—Author says that his results obtained by methods given have been upheld in court in suits for infringement of Straub cinder block patent. After explanation of method for qualitative examination to determine coarse aggregate used and some other things a method is given for analyzing concrete of cement and cinders. The sample is digested with 50 cc. 10 per cent HCl and insoluble determined. As cinders are 95 per cent insoluble and cement is about 98 per cent soluble, the insoluble found divided by 95 will be practically the percentage of cinders. Where sand, cinders and cement make the concrete, insoluble found as before is dried and weighed. Then sand is separated by Thoulet's heavy solution in which cinders float while sand sinks. With concretes of cement sand and slag, some of slag is removed and analyzed for insoluble, soluble silica, and lime and apparent specific gravity and loss on ignition are determined. The proportion of slag may be figured from either soluble silica or lime in the concrete and also in the slag. A similar method is used with concrete of cement, sand and limestone, a sample of the limestone being removed and analyzed separately. The limestone content may be found by formula which includes the CO_2 contents of the concrete and the limestone. With concretes of unknown composition there must be a careful visual examination and the use of physical methods, which are described, in addition to chemical analysis.—EDMUND SHAW

Relation between durability of concrete and durability of aggregates. F. H. JACKSON. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—Basic requirements for durability are: the use of sound and durable aggregates, and maximum resistance to the entrance of water. The aggregates play a double role since the range of sizes plays an important part in producing impermeability. The characteristics of aggregates which affect their durability in concrete, and the effects of other factors such as permeability, water absorption, etc., are not well understood, and thorough investigations are needed. Concerted laboratory studies looking toward the formulation of standard tests for durability, and field investigations to correlate laboratory and structural experience are urged. Outlines for research work are presented.—HIGHWAY RESEARCH BOARD

Special investigation—curing of concrete pavement slabs. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—Progress report setting forth the facts established by study of the available data with respect to strength, surface scaling, and volume changes as affected by the various well known curing methods, together with the tentative conclusions drawn by the committee. The report will include complete summaries of the data collected by the committee.—HIGHWAY RESEARCH BOARD

Durability of concrete in highways and highway structures. C. H. SCHOLER. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—General discussion of the factors involved . . . Types of disintegration observed as evidence of a lack of durability . . . Report of laboratory

and field investigations of durability as affected by method of testing, size and shape of specimens, method of sampling, character of aggregate, quality of cement paste, permeability and absorption as a factor in disintegration, and effect of water-proof coatings. An accelerated freezing and thawing test is presented as a means of testing the resistance of concrete and concrete aggregates to weathering agencies.—HIGHWAY RESEARCH BOARD

Concrete dams in Norway. *Report*, Norwegian Society of Engineers, July, 1930, 272 p., Den Norske Ingenioersforening, Oslo (Norway).—To investigate effect of water action when under hydraulic pressure on dams of concrete, the Norwegian Society of Engineers in Oslo have made thorough examination of 88 of more important concrete dams in Norway, some of which are more than 30 years old. These investigations were started in the summer 1926, and this is first report by committee. It was found that very few of the dams were uninjured and that injuries were not evenly distributed over dams, thus showing that proportions of concrete mixture must have varied during their construction. Joints had most of the injuries. Organic matter, iron and manganese substances were accumulated on the injured parts. Though none of the dams was found to be very seriously damaged, committee advised repair of injuries. Main reason for injuries is said to be chemical action of water. Thus water will penetrate cracks caused by temperature changes and frost and start to remove soluble parts of concrete. Flood water is known to be more or less acid and is therefore lime dissolving. Concrete mixture was found in most cases to be too lean, and it is pointed out that sooner or later a concrete structure under hydraulic pressure would be completely destroyed by this acid water. Use of membranous water proofing is suggested for protection against temperature cracks but no means has been found to protect this layer against mechanical action of water. Interesting suggestion proposes placing thin watertight concrete slab in front of dam, to make concrete dam dry by keeping air space between slab and dam. This type construction was used for Ringedal dam, 100 ft. high. Slab was 8 in. thick at top and 18½ in. thick at bottom, supported by columns with spiral reinforcing. Air space between slab and dam was 6.6 ft. Horizontal spacing of columns was 7½ ft. and vertical spacing varied from 10 ft. to 6 ft. at bottom.—ODD ALBERT

Investigations on protection of concrete against aggressive solutions. OTTO GRAF. *Zement* (Germany), Oct. 2, 9, 16, 30 and Nov. 6, 1930, V. 19, No. 40-41-42-44-45, p. 936-41, 970-4, 995-8, 1041-3, 1066-8.—Best protection of concrete is obtained, when aggressive waters are kept away from concrete. This fact is very often not sufficiently taken into consideration although it may be possible by certain changes of design of structure. Special shaping of structure may also lead to same effect. Running water has in general greater effect on concrete than standing water. When concrete is only partly immersed in aggressive water, dividing line between water and air is subjected to greatest corrosive effect. Water is raised in concrete body by capillary attraction, and salt contents in upper portion is increased by evaporation. Studies were made in order to find cements most resistant against sulphate waters, waters with great contents of uncombined carbon dioxide, certain salt solutions and organic media. Iron portland cement with low lime content loses less strength than normal portland cement when immersed in linseed oil. After storage in 10 per cent solution of magnesium sulphate, iron portland cement lost in 15½ months 18 per cent of its 28-day strength, while high early strength portland cement and blast furnace slag cement showed gains from 1 to 9 per cent. In magnesium chloride solution, cubes of high early strength cement were destroyed, iron portland cement lost 33 per cent and blast furnace slag cement gained 6-7 per cent in strength. Degree of fineness is very important: finer cements show less disintegration than coarser ones. Various cements were tested in different mixtures with sand and different consistencies and stored under magnesium sulphate and magnesium chloride solutions. Further sub-

ject of investigation was effect of cement content and gauging water on resistance against movement of liquids in concrete body. Graduation was studied which gives greatest resistance against chemical attack. Mixtures of 1:3 cement:sand were more resistant than 1:6 mixtures. Amount of mixing water should not exceed absolutely necessary limit. Presence of 3 per cent clay in sand caused great losses in strength when specimens were placed in aggressive solutions after a seven day moist closet storage, but retrogression did not take place when specimens were dried for 35 days before submitting to test. Additions of trass seem to improve concrete resistance. Finally influence of storage and finishing on concrete durability were studied.—A. E. BEITLICH

Fire damage in Riga. ED WEISS. *Beton Eisen* (Germany), Oct. 5, 1930, V. 29, No. 19, p. 344-348.—Buildings 134, 135 and 218 of Prowodnik Rubber Company, leased to the Soviet Government for flax storage suffered severe fire damage on April 11, 1930. Units 134 and 135 are five-story reinforced concrete structures, each three bays wide and fifty-eight bays long, measuring 92 ft. x 874 ft. in plan. Unit 218, a one-story structure with steel roof trusses, and measuring 99 ft. x 874 ft. in plan occupies the 99 ft. space separating these two buildings. Structures were erected in 1913 through cooperation of German and Swiss construction company. There is no indication of faulty construction but there is much to criticise in design. Beams and columns were evidently figured as non-continuous units with no regard for frame action—usual practice in Russia at that time. These units were tied together at points with small amount of steel and with small haunches. Design would not have been permitted according to Russian standards of 1914. Long spans and light sections give impression of weakness. Temperature joints divide structures into lengths of approximately 130 ft. It is surprising that wind forces for which no provision was made have had no visible effect throughout the 16 years during which buildings have been exposed to severe sea-storms. There were no fire-walls in any of three structures. At time of fire, flax to a depth of 10 ft. with open aisles along the columns and exterior walls, was stored on lower 3 floors of Unit 134, in Unit 218 and on ground floor and part of second floor of Unit 135. Fire was combatted by 30 hoses and 10 fire boats. An effort was made to flood the flax but to avoid striking hot concrete with cold stream. Steel beams, with lower surfaces exposed for attachment of shafting, reached white heat and concrete was heated in some cases to red glow. Columns in burning stories displayed a progressive outward bowing until collapse of structure. A deafening rattle like machine gun fire, perhaps due to failure of reinforcement, immediately preceded collapse. A total length of 620 ft. of Unit 134 collapsed after estimated exposure to fire of from 4 to 6 hrs. Portions still standing seem to indicate that cement was burned out of the concrete but that sand and gravel suffered no damage. In many cases column steel bulged and concrete scaled off, often for considerable depth into the core. The horizontal cracking and outward bowing evident in exterior columns at floor levels may be due largely to fact that these columns were comparatively fixed against lateral movement, at the foundation and at upper stories (where no flax was stored). Heating of slabs to 1110° F. and to 1830° F. would lead to lateral expansion of 4.5 in. and 7.1 in. respectively, at intermediate floor levels. These lateral forces would be sufficient to crack columns and to force them outwards. Destructive effect of a stream of water on hot concrete is shown by a photograph in which path of stream is indicated by a deep gouge in slab soffit and entire removal of concrete for one foot length of beam. The 9500 short tons of flax lost are valued at $1,750,000 while building damage is $250,000. Some insurance experts have expressed opinion based on this fire, that steel covered with brick or tile is more fireproof than reinforced concrete. Structure itself contradicts this conclusion for lean concrete used in upturned portion of spandrels broke as a unit at limits of various pours but showed little surface damage. A few brick walls on ground floor were completely destroyed. Mortar was burned out and the bricks burst.—A. A. BRIELMAIER

ENGINEERING DESIGN

BRIDGES

Pneumatic caisson foundations for Japanese bridge. J. MASAKE. *Eng. News Record*, Nov. 27, 1930, V. 105, No. 22, p. 848-850.—A handsome concrete-arch bridge with stone facing has been built to replace old wooden bridge across Shinano River at Niigata, a city on north side of main island of Japan. The bridge consists of six spans of hingeless concrete arches, two each of 154 ft., 151 ft., and 142 ft.; in addition, there are two 48-ft. two-hinged land spans. A headroom of 18½ at low water is sufficient for the craft on the river. The riverbed is composed of layers of fine and coarse sand to depth of 80 ft. Pneumatic caissons were used for piers and abutments of main bridge. Sand from caissons was used in making concrete, along with river gravel and Japanese portland cement.—D. E. LARSON

Vierendeel bridges. E. BALIS. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930. Abstracted from translation in *Concrete Constr. Eng.* (England), Nov., 1930, V. 25, No. 11, p. 632-34.—In Belgium the Vierendeel girder is widely used and shows an economy of about 20 per cent over ordinary steel lattice structures, though when reinforced concrete is used the saving is not so great. The actual stresses in these bridges are about 6 per cent less than theoretical stresses. A closer agreement would require laborious calculations. Two classes of this type of bridge are in general use: (1) the bowstring and (2) the arch with monolithic decking.—JOSEPH MARIN

Reinforced concrete bridge at Wisbech. *Concrete Constr. Eng.* (England), Nov., 1930, V. 25, No. 11, p. 609-12.—This reinforced concrete bridge now in the course of construction over the river Neme, at Wisbech, will be the largest span portal type bridge in Great Britian. Clear span will be 92 ft. 6 in. and width between parapets will be 45 ft. Choice of suitable design was influenced by considerable rise and fall of tides at bridge site. The maximum rise in tide is 15 ft. The type of construction adopted consisted of six main girders ranging in depth from 3 ft. 9½ in. to 3 ft. 7 in. with deep curved haunches at the ends. Width of beams varied from 26 in. to 37 in. Details of bridge and method of construction are given.—JOSEPH MARIN

Design of arched bridges with fixed supports. H. CARPENTER. *Concrete Constr. Eng.* (England), Nov., 1930, V. 25, No. 11, p. 611-23.—Object is to develop a simplified method of design for arches with fixed supports. Tables are given for calculating stresses in parabolic, open and filled spandrel arches, with different rise-span ratios and varying moment of inertia. Simplification in the calculations is obtained by designing ring to coincide with line of pressure for dead load. In this way an economical design is obtained and stresses due to arch shortening are easily computed. Expressions are derived for horizontal thrust due to dead load and arch shortening, and for bending moments due to arch shortening both at crown and springing. Values of these thrusts and moments are given in tables for different ratios of the moment of inertia at the crown and springing, and for different rise-span ratios. A table is given for each of the three types of fixed arches considered. Similar tables to the above are given for changes due to temperature, giving the values of horizontal thrust and bending moments at crown and springing produced by changes in temperature.—JOSEPH MARIN

Buildings

A new garage construction in Frankfurt a. M. (Germany). H. Craemer. *Zement* (Germany), Nov. 6, 1930, V. 19, No. 45, p. 1068-9.—Building of taxicab company is made entirely of reinforced concrete in modernistic style. Floor constructions of special design show interesting features. Details of columns, construction of windows and arrangement of storage and repair shops are illustrated.—A. E. Beitlich

An example of the mechanical solution of a statically indeterminate structure. H. W. Coultas. *Structural Eng.* (England), Oct., 1930, V. 8, No. 10, p. 344-366.—A complete analysis by means of Begg's Deformeter Apparatus is given for a six story frame two bays in width. Method of test and reduction of data for full size structure are given.—V. P. Jensen

Static consideration of concrete mantle of supports in steel skeleton structures. Leopold Berger. *Zement* (Germany), Oct. 23, 1930, V. 19, No. 43, p. 1018-20.—When steel columns of large skeleton structures are provided with concrete mantles it protects them against rust and also increases supporting strength. Great savings can be obtained by decreasing dimensions of steel column and reinforcing concrete with longitudinal irons. This combination is especially applicable to supporting columns of basements and lower floors. Example is given and calculation shows savings of 45 per cent of construction costs.—A. E. Beitlich

Combining steel and concrete framing to effect economy. *Eng. News Record*, Nov. 27, 1930, V. 105, No. 22, p. 844-845.—An unusual combination of three types of structural framing in the 27-story Buckingham Building, 59 East Van Buren St., Chicago, includes built up steel columns of two different types, with both steel framing and concrete-beam framing, and also reinforced concrete columns with concrete-beam framing. Purpose of this combination was partly to effect economy and partly to keep column sizes within prescribed limits. Built up steel columns of H-section are used as far as the eleventh floor. Above the eleventh floor interior columns are also of steel, but of the Gray type, to the eighteenth floor, above which are spirally reinforced concrete columns. With columns varying in design at different heights, special methods were required for splicing the different types of steel and concrete columns. Typical details of these connections are shown. A two-way concrete floor of tile and joist type is another special feature of this building, and is used with both steel and concrete framing. Joists in both directions form a cellular construction with hollow tile filling in the rectangular spaces. Flat pieces of tile are placed under the concrete joists, being supported by dovetailed grooves in the filler tiles, so there is continuous tile surface for ceiling plastering. The floor slab over filler tiles is 2 in. thick and depth of tile is 4 in. Advantages of this type of floor construction are shallow depth and low dead load.—D. E. Larson

Rigid rectangular frame foundation for Albany Telephone Building. G. W. Glick. *Eng. News Record*, Nov. 27, 1930, V. 105, No. 22, p. 836-838.—A reinforced concrete foundation mat and two superimposed basement stories of reinforced concrete designed to act together as a rigid frame structure form interesting and unusual foundation for new section "B" of main telephone building at Albany, N. Y. This building recently completed by the New York Telephone Co. as extension to its existing plant, is 94 by 167 ft. with 3 basements and 11 stories of super-structure. Two factors made the foundation design complicated and important. These were: (1) character of the soil; and (2) necessity, because of delicate mechanism of telephone exchanges, that the building be free from unequal settlement. Building rests on clay formation over 100 ft. deep. Other buildings on this soil have settled over a long period

of time before finally coming to rest as the clay became stable under new load condition. This fact, with considerable economy in cost, led to choice of a continuous foundation mat which could distribute weight of building over its entire area. The substructure is advantageously combined into a rigid-frame, two-story-and-mat structure acting as a unit to resist unequal settlement, variations in loads and the undesirable center sag. Such a frame is virtually a truss without diagonal members and is known as the Vierendeel truss. To provide for expected settlement of building, all floors were set 1½ in. higher than those of adjoining building. Inspection of new building made in February, 1930, showed no settlement cracks in substructure or superstructure.—D. E. LARSON

Fire damage in Riga. (See PROPERTIES OF CONCRETE.)

DAMS

Stresses in gravity dams by principle of least work. B. F. JAKOBSEN. *Proc. Am. Soc. C. E.*, Sept., 1930, V. 56, No. 7, p. 1613.—Data are cited from English tests on model dams which show a non-linear stress distribution on horizontal planes. When the principle of least work was substituted for the usual assumption of a linear stress distribution in a theoretical investigation, a stress curve similar to that found in the English tests resulted. The proposed theory gives a higher bending stress at up-stream face and lower at down-stream face. It is believed that the principle of least work method will more nearly approach the true stresses than will results obtained by usual method. Belief is supported by explanations and mathematical reasoning. Previous works of Vogt, Cain, and others are cited frequently. The whole discussion applies to the masonry dam, which is usually made of concrete.—H. J. GILKEY

Circular concrete arch dam designed by simple method. R. P. V. MARQUARDSEN, *Concrete*, Nov., 1930, V. 37, No. 5, p. 33-38.—This is the second article on this method. The design formulas were stated dogmatically in October issue of *Concrete*. Present paper contains the derivations of the various formulas. The cylinder formula is used. Total compressive stress on any cross section of a hollow-cylinder wall is expressed. For purpose of analysis, the arch is assumed to be cut at the crown and to move due to radial loading, temperature and shrinkage stresses, and settlement of supports. Equations for these stresses are derived. Arch is then treated as a unit, fixed at both ends, and subjected to other stresses in addition to above mentioned ones. Bending moments, angle changes and horizontal movements are discussed and equations derived. Unit fiber stress for combined direct and bending action is derived and stated in a simple equation.—N. H. ROY

Blasting a precast dam into place. C. P. DUNN. *Civil Eng.*, Dec., 1930, V. 1, No. 3, p. 159-164.—One of most interesting and difficult features in building of a 200,000 kw. hydro-electric plant at Chute à Caron on the Saguenay River in northwestern Quebec was the diverting of swift stream by building on land a heavy reinforced concrete dam and dumping it bodily into place. Essential features involved in this scheme were (1) a fixed pier, relatively massive, to carry greater part of weight and thrust; (2) a small pier carrying part of weight, to be blasted away; (3) a cylindrical rolling face on fixed pier so designed and placed that precast dam would fall into an accurately predetermined position. Standing on end, the dam was 92 ft. high, 45 ft. thick up and downstream, and had a maximum depth of 40 ft., the bottom being contoured to fit river bottom as dam fell into place. Reinforcing consisted largely of old steel cables. Upon blasting the small pier away, the dam fell accurately into place and was not shattered by impact although a few small hairlike cracks appeared.—D. E. LARSON

The Boulder Canyon project. *Eng. Con.*, Nov., 1930, V. 37, No. 5, p. 398.—The Hoover Dam, of gravity-arch type, will rise about 727 ft. above foundation rock and raise water surface 582 ft. Length of crest will be about 950 ft., width at base 650 ft., and at top, 45 ft. River will be diverted during construction by means of coffer dam and four 50-ft. diameter concrete lined tunnels through the canyon walls. Only openings through the dam will be eight metal-lined conduits 6 ft. 9 in. in diameter for carrying the low flow of the river when the diversion tunnel plugs are being poured. The spillway will be two glory-hole type spillways discharging through 50-ft. diameter vertical shafts into the outside diversion tunnel. Tentative plans call for a power plant to develop one million horsepower. The All-American Canal will be 75 miles long and the Coachella branch 115 miles long. The dam and power plant will require 4,510,000 cu. yd. of concrete masonry. Five and one-half million bbl. of cement and nineteen million pounds of reinforcing steel will be required —N. H. ROY

The buttressed dam of uniform strength. HERMAN SCHORER. *Proc. Am. Soc. C. E.*, Nov., 1930, V. 56, No. 9, p. 1947.—The buttressed concrete dam, of which Ambursen and multiple-arch are best known illustrations, consists of three distinct members: deck, buttress, and foundation. The buttress is generally most important item as regards quantity of concrete. This has been designed on basis of vertical stress components and horizontal shearing stresses. It is proposed to substitute for buttresses a series of arched columns designed on basis of principle stresses. To eliminate trial computations, water pressure acting on an elementary deck area is considered to be transmitted to foundation in most direct manner by elementary arched columns. These elementary columns can then be combined into a monolithic buttress of uniform strength or they may be separated from one another by continuous joints to eliminate secondary stresses due to shrinkage, temperature changes, etc. Old method has sometimes been unsafe since consideration of shears on the horizontal section failed to take into account important components of stress. Proposed method offers economy and rationalizes design. The paper outlines mathematical analysis of method and gives references to detailed derivations and more complete manuscript on file in the Engineering Societies Library, New York.—H. J. GILKEY

Concrete dams in Norway. (See PROPERTIES OF CONCRETE.)

MISCELLANEOUS

Economical bases for stanchions—"Controvertist." *Structural Eng.* (England), Nov., 1930, V. 8, No. 11, p. 402-405.—For a steel column supported on a concrete base, the pressures on the sides of base have been included in computing the resistance of base to overturning moment due to wind pressure. Connection of column to base is considered for conditions where column is embedded in base and where column rests on top of the base.—V. P. JENSEN

Economic dimensions and shaping of slab girders of reinforced concrete under consideration of their own weight. ALPHONS CHMIELOWIEC. *Oesterr. Ing. Arch. Ver.* (Austria), Oct. 10, 1930, V. 82, No. 41-42, p. 360-1.—Work which was done by Mayer, Barck and Saliger on calculation of reinforced concrete structures is discussed. Based on mathematical considerations, a way is shown for better economic designs of slab girders in reinforced concrete construction practice.—A. E. BEITLICH

Reinforced concrete design simplified. JAMES R. GRIFFITH. *Concrete*, Nov., 1930, V. 37, No. 5, p. 31-32.—Chart 1 gives depth of concrete slab and area of steel necessary for balanced reinforcing. The factors employed are: span in feet, moment coefficient, live load, slab thickness and steel area. An

allowable steel stress of 20,000 lb. per sq. in., concrete stress of 1200 lb. per sq. in., and n equal to 10 are used. This chart may also be used for obtaining steel area for a slab thicker than is warranted for span and load conditions, using the steel required for the lesser conditions although in a slab thicker than necessary. This approximation is on the side of safety.—N. H. ROY

Austrian tests on concrete columns with high quality steel reinforcements. R. SALIGER. *Oesterr. Ing. Arch. Ver.* (Austria), Oct. 10, 1930, V. 82, No. 41-42, p. 361-2.—In connection with a comprehensive investigation on concrete columns with different reinforcements, conducted at laboratory for testing materials in Berlin-Dahlem (Germany) and at technical testing laboratory in Vienna (Austria), a number of column tests with high quality steels were made. Cross-section of steel varied from 4 to 14 per cent of total column cross-section. Columns were 9.8 ft. and 4 ft. long. Bearing strength was surprisingly high, and necessary cross-section of concrete column was not greater than cross-section of a riveted or welded steel column of same strength. Further tests are in preparation.—A. E. BEITLICH

Solving rectangular concrete members subjected to bending and direct stress. L. C. MAUGH. *Eng. News Record*, Nov. 6, 1930, V. 105, No. 19, p. 723-724.—The problem of designing rectangular reinforced concrete sections for bending and direct stress is now frequently encountered in use of rigid frames. In this article, author presents formulas and a diagram for design of such members. Numerical operations are made in same sequence as those for ordinary beams. This method is more direct than the methods usually presented in textbooks and the chances for numerical mistakes are less. Concrete is assumed to resist no tension and to have a constant modulus of elasticity.—D. E. LARSON

Folded plates (Faltwerke) and their application in reinforced concrete construction. H. CRAEMER. *Zement* (Germany), Oct. 16, 23, 1930, V. 19, No. 42-43, p. 990-2, 1020-2.—Author extends his studies concerning economic design and construction of reinforced concrete plates (c. f. *Zement*, July 24, 1930, V. 19, No. 30, p. 703-8; *J. Amer. Concr. Inst.*, Nov., 1930, V. 2, No. 3, Abstr. Sect. p. 72) on combination and arrangements of monolithic concrete plates junctions of which form certain angles. Analysis are given of stresses which occur in such combinations, and it is shown how this construction principle can be applied with great advantage to practice of silo and bin construction. Furthermore, consideration is given to construction of concrete roofs and multiple arrangements of this type. Writer refers to article by Ehlers in *Bauingenieur* (Germany), Feb. 21, 1930, V. 11, No. 8, p. 125-32 (*J. Amer. Concr. Inst.*, Nov., 1930, V. 2, No. 3, Abstr. Sect. p. 84) on a similar subject.—A. E. BEITLICH

Theory of similarity and models.* BENJAMIN F. GROAT. *Proc. Am. Soc. C. E.*, Oct., 1930, V. 55, No. 8, p. 1803.—Although Newton's principles of similarity and the theory of models were enunciated 250 years ago, the use of models by engineers is recent. Models often present the best form of preliminary analysis for constructing engineering works of great magnitude. The mathematical background that underlies the proper use of models is presented and attention is called to current fallacies. It is suggested that materials, including fluids should be sought, made, and arranged so as to adapt and make them available for service in models.

**Abstractor's Note:* It is deemed desirable to call the attention of the A. C. I. constituency to this paper because of the increasing use of models in connection with concrete design.—H. J. GILKEY

Concrete stadium for $6.60 per seat. *Eng. News Record*, Nov. 6, 1930, V. 105, No. 19, p. 721-722.—A concrete stadium has recently been designed for Sacramento Junior College at Sacramento, Calif., at a cost of $6.60 per

seat. By developing a design structurally independent of floorslab and using timber seats and walkways that could be put in place with a minimum of labor, cost of 22,000 seat structure was kept down to $145,000. The structural scheme consists essentially of concrete columns 14 in. square spaced 16 ft. apart both ways. These columns are connected at top by reinforced concrete girders carrying one intermediate beam each way, which reduces spans to 8 ft. With this span a 2 by 12-in. plank is ample for carrying maximum calculated load of 100 lb. per linear foot. Planks of this size were used both for seats and walkboards, the seat being stiffened by a 1 by 6-in. edge board.—D. E. LARSON

Grade separation structures untangle traffic jams. ROBERT C. KINGERY. *Concrete*, Nov., 1930, V. 37, No. 5, p. 17-19.—Four major types of structures or plans are employed in separation of intersecting highways. First type comprises two highways at different levels, with no means of turning from one highway to the other. In the second type there is an elevated structure which carries the central part of one of the highways over and across the full width of the other, all other pavements and the sidewalks on both roads remaining at grade. Third type is most desirable from the standpoint of abutting property owners. The central part of one highway is depressed, all other pavements and sidewalks remaining at grade. Fourth type is well suited to crossings where public property is available. One highway is partly depressed and other partly elevated. Diagonal lanes serve as connecting links between highways. Another effective arrangement which does not involve actual separation of grades is the traffic circle. It keeps traffic moving in both directions on both roads, although traffic on the circle itself is all in one direction, moving counter-clockwise.—C. BACHMANN

Analysis of continuous frames by distributing fixed-end moments. HARDY CROSS. *Proc. Am. Soc. C. E.*, May, 1930, V. 56, No. 5, p. 919-928.—While not restricted to concrete, the method of analysis is especially applicable to concrete construction since the method is intended to be an aid in obtaining the moments, shears and thrusts required in the design of complicated continuous frames from the reactions which can themselves be found by more or less standard means. The method is restricted by condition that joint must not be displaced but even this case can be indirectly treated. The writer emphasizes the fact that he is setting forth a *method of analysis* for the benefit of those who recognize that values of moments and shears cannot be found exactly but who desire a method of analysis that will combine reasonable precision with speed. The method is therefore one of successive approximations rather than an approximate method. Moreover it is a method rather than a treatise.—H. J. GILKEY

Small movements in concrete. W. H. GLANVILLE. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930. Abstracted from *Concrete Constr. Eng.* (England), Nov., 1930, V. 25, No. 11, p. 634-43.—The paper deals with work of Building Research Station on small movements in concrete. From test data an empirical formula is obtained for the stress in reinforcing steel of concrete members due to shrinkage of concrete. Coefficients obtained from tests are given that are to be used in the empirical formula. Tests were made to determine the creep or flow of concrete under load for both plain and reinforced concrete. For plain concrete the effect of the following factors on flow of concrete was studied: (1) stress, (2) type of cement and age at loading, (3) cement content and (4) storage conditions. Tables are given for each of these factors giving the amount of creep. The tests show that (1) creep is approximately proportional to applied stress, (2) rapidity of hardening directly influences creep to considerable degree, (3) creep is approximately proportional to quantity of aggregate, and (4) influence of age of concrete at the time of loading is appreciable for about the first month.—JOSEPH MARIN

Nomogram for calculating the area of any number of bars of the same dimension. JORGE QUIJANO. *Ingenieria* (Mexico), May, 1930, V. 4, No. 5, p. 204.—A simple nomographic chart, one of a series, for use in reinforced concrete design, to compute areas of steel reinforcement. Left hand scale, dimension of bars, center scale area of bar and right hand scale number of bars, all in metric units. Explanation of use given on chart.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating columns without spiral reinforcement (central load). JORGE QUIJANO. *Ingenieria* (Mexico), May, 1930, V. 4, No. 5, p. 209.—A simple alignment chart, one of a series, for use in reinforced concrete design, to solve formula $P = [A_c + (n - 1) A_s] f_c$. Metric units used throughout. Left hand scale A_c, middle scale P and right scale A_s for $n = 15$, $f_c = 500$ lb. per sq. in., $h/R < 40$. Explanation of use given on chart.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating the pressure of earth (or water). JORGE QUIJANO. *Ingenieria* (Mexico), June, 1930, V. 4, No. 6, p. 227.—Alignment or nomographic chart for use in computing earth pressure for concrete retaining wall design by Rankine's formula. Explanation of use given on chart. All in metric units.—C. G. CLAIR AND M. N. CLAIR

Nomogram for economical design of T-beams. JORGE QUIJANO. *Ingenieria* (Mexico), June, 1930, V. 4, No. 6, p. 237.—A nomographic chart, one of a series for use in reinforced concrete design and investigation, solving the relations $d = \sqrt{\frac{r}{b^1}\frac{M}{f_s}} + \frac{t}{2}$ and $M = A_s f_s (d - t/2)$. Left hand scale $(d - t/2)$, middle scales M/f_s and A_s and right hand scale b^1/r. Explanation of use given on full size chart. All in metric units.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating the allowable distance between abutments of vertical or inclined reinforced concrete slabs as determined by diagonal tension and shear. JORGE QUIJANO. *Ingenieria* (Mexico), June, 1930, V. 4, No. 6, p. 253-254.—A nomographic chart for use in designing or investigating buttressed retaining walls which solves the relation $T = S (v - 2.8) b$. Explanation of use is given on a separate page. All in metric units.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating simple slabs and rectangular beams. JORGE QUIJANO. *Ingenieria* (Mexico), July, 1930, V. 4, No. 7, p. 280.—A simple alignment or nomographic chart, one of a series of such charts, for use in reinforced concrete design and investigation, solving the relations $d = 0.3558 \sqrt{M/b}$ and $A_s = 0.002532 \sqrt{Mb}$ for $n = 15$, $f_s = 18{,}000$ lb. per sq. in. and $f_c = 700$ lb. per sq. in. Left hand scale or line d, middle scales M and A_s, and right hand scale b. Explanation of use given on chart. All in metric units.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating slabs or beams with a certain degree of end restraint. JORGE QUIJANO. *Ingenieria* (Mexico), July, 1930, V. 4, No. 7, p. 291.—A simple alignment or nomographic chart, one of a series, for use in reinforced concrete design and investigation, solving the relation between A_s, d and M for $n = 15$, $f_s = 18{,}000$ lb. per sq. in. and $f_c = 700$ lb. per sq. in. Left hand scale or line L, middle scales A_s and d, and right hand scale W. Explanation of use given on chart. All in metric units.—C. G. CLAIR AND M. N. CLAIR

Nomograph for calculating slabs or beams with a certain degree of end restraint. JORGE QUIJANO. *Ingenieria* (Mexico), Sept., 1930, V. 4, No. 9, p. 342-343.—A simple alignment chart for use in reinforced concrete design solving the relation between A_s, d and M for $n = 15$, $f_s = 20{,}000$ lb. per sq. in.

and $f_c = 800$ lb. per sq. in. Left hand scale L, middle scales A_s and d, and right hand scale W. Explanation of use given on chart and next page.—C. G. CLAIR AND M. N. CLAIR

Nomogram for determining the tension in the steel of simple T-beams. JORGE QUIJANO. *Ingenieria* (Mexico), April, 1930, V. 4, No. 4, p. 173.—A simple alignment chart, one of a series, for use in reinforced concrete design and investigation, solving the relation $M = 0.9\,dT$. Left hand scale T, center scale M and right scale d, all in metric units. Explanation of use given on chart.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating the moment due to the weight of a slab or beam. JORGE QUIJANO. *Ingenieria* (Mexico), April, 1930, V. 4, No. 4, p. 177.—A simple alignment chart, one of a series, for use in reinforced concrete design, solving the relation $M = 0.0003\,b\,(d + e)l.^2$ Left hand scale l, center scale M/b and right scale $(d + e)$, all in metric units. Explanation of use given on chart.—C. G. CLAIR AND M. N. CLAIR

ROADS AND PAVEMENTS

The design of a concrete mixture. J. E. MYERS AND MARK MORRIS. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—Detailed description of steps involved in design of a mixture for concrete to be made of certain specific materials to have an average crushing strength of 4000 lb. per square inch at 28 days, to be of suitable consistency for pavement work, and to require the use of predetermined quantities of materials. The design was based upon methods proposed by Talbot and Richart with some variations. Previous experience with one of the materials used in this case was reported in the Seventh *Proceedings* of the Highway Research Board. Use of the designed mix on 15 miles of pavement, showed that the concrete was of satisfactory consistency, that the average strength was slightly in excess of the requirement, and that the cost of the materials used was 0.03 per cent less than the estimate.—HIGHWAY RESEARCH BOARD

Boulevard and Great Belgrano Park, planned for the City of Rosario. *Magazine Tecnico* (Argentina), June, 1930, p. 16-17.—Department of Navigation and Ports of City of Rosario, province of Buenos Aires, Argentina, proposes to construct avenue and park along Parana river. The avenue is to provide a proper view of river and the park to give proper setting for historical spot where the flag created for Belgrano first was unfurled. Two types of cross section are proposed for the avenue both occupying a total width of 164 ft. Type A cross section has two roadways 36 ft. wide, foot paths on each side of these roadways of 19 ft. 6 in. and 10 ft. 0 in. width respectively, and a central park or garden section 33 ft. wide. Type B cross section has two roadways 20 ft. 6 in. wide with footpaths of 19 ft. 6 in. on each side and a central park or garden section 45 ft. wide. Roadways are to be of reinforced concrete of 1:2:3 mix, that for the type A 7 in. thick with 9.2 lb. of steel per sq. yd. and for type B 6 in. thick with 9.2 lb. of steel per sq. yd. It is estimated that plan A would cost $1,425,-816.17 and plan B $1,087,204.60.—C. G. CLAIR AND M. N. CLAIR

FIELD CONSTRUCTION

BRIDGES

Bridges and roads of the nation (Argentina). *Magazine Tecnico* (Argentina), March, 1930, p. 15-26.—A review of progress during 1929 on various projects with details. Numerous bridges of reinforced concrete have been completed or are in the process of construction. The bridges are generally of reinforced concrete arch type with some of beam and girder. New road construction includes considerable concrete.—C. G. CLAIR AND M. N. CLAIR

Construction of Pancevo bridge over river Danube near Belgrad (Serbia). MAX HEINICKE. *Bautechnik* (Germany), June 6, 1930, V. 8, No. 24, p. 354-7.—Structure is truss bridge with 7 spans, which rest on 8 reinforced concrete piers. Approach on south side is reinforced concrete arch bridge with 5 spans. Length of truss bridge is about one mile, and of reinforced concrete arch bridge 393.7 ft. Distances between river piers from center to center are 528.2 and 531.5 ft. Spans of concrete bridge are about 83.7 ft. River piers are founded on layer of very hard clay 91.8 ft. below normal water level. Caisson method was used for their foundation; caissons are 95.1 ft. long, 41.0 ft. wide and 24.6 ft. high. Usually two piers were placed at same time, two travelling cranes being used for placing caissons and for transportation of concrete. Concrete was mixed in one-yard mixer which, together with aggregate silo and crane, was mounted on a barge. Piers and foundation slabs were made of 1:8 mix and top slabs of 1:4 mix. Parts of piers exposed to heavy ice pressures are lined with layer of natural stones. Depth of foundations of piers for reinforced concrete bridge is determined by depth of clay layer. One pier was placed using compressed air method, and two were made in open excavation with steel sheet piling of Larrsen type.—A. E. BEITLICH

The bridge over the marsh and river Warthe near Fichtwerder (Germany). KARL BERNHARD. *Bautechnik* (Germany), May 16 and 30, 1930, V. 8, No. 21-23, p. 311-5, 338-42.—Highway bridge over marsh and river consists of two parts: one steel structure of 459.3 ft. length, which crosses river at right angle and rests on three concrete river piers, and one reinforced concrete bridge over marsh, which is 1653.6 ft. long, resting on 25 piers. Concrete bridge approaches river bridge at slight angle and artificial island was built at their junction. Center opening in river is 295.3 ft. wide while two side openings are 82 ft. each. Piers of concrete bridge are placed in alternating distances of 78.1 and 82.0 ft. Roadway rests on 3 main longitudinal flat slab girders, spaced 7.4 ft. apart. Height of girders is 4.8 ft. Several drawings show details of their construction. River piers were built using compressed air method and consist of foundation 13.1 ft. wide protected against aggressive waters by brick wall, and upper shaft, 8.2 ft. wide. Foundation of piers of concrete bridge rests on concrete piles of 15.7 in. diameter. They were driven about 6 ft. into sound underground. Twelve piles support one pier. Article is accompanied by 35 illustrations which explain details of structure and portray all stages of construction.—A. E. BEITLICH

The reconstruction of the Niddatal bridge near Assenheim in Oberhessen (Germany). METZIG. *Bautechnik* (Germany), Aug. 22, 1930, V. 8, No. 36, p. 540-4.—Old railroad bridge of steel construction was rebuilt and provided with 5 reinforced concrete piers to replace 8 old steel structures. New piers were placed on new foundations. Excavations were protected by steel sheet pilings, 26.5 and 45.9 ft. long, of Larrsen type, driven from 16.4 to 23 ft. deep into sound underground. Bridge has two openings of 1490 ft. at each side and two openings of 1863 ft. between three middle piers. Foundations of piers consist of reinforced concrete slabs, 49.2 by 70.2, 43.9 by 70.2, 38.7 by 70.2 and 25.6 by 70.2 ft. Special care was required for one end pier foundation, which is directly by side and below foundation of old pier. Concreting was carried out in two sections which are tied together by heavy reinforcements. No protective coatings were necessary, since chemical analysis of groundwater showed absence of aggressive agents. Gravel was delivered by railroad cars and dumped from bridge through long wooden chutes (to prevent separation of different sizes) to mixer. Total of 157 cu. yards gravel was unloaded daily. Mixer had capacity of 17½ cu. ft. Construction period lasted five months.—A. E. BEITLICH

Concrete pits of bascule bridge resist high water pressure. *Concrete*, Nov., 1930, V. 37, No. 5, p. 13-16.—Concrete in the walls and floors of machinery pits at both abutments of the double leaf, Wabash Ave. bridge, at

Chicago resists a pressure head of 25 ft. of water. Pits comprise space formed by the four walls of the abutments. Floor is concrete slab 5 ft. thick and the entire structure acts as a unit supported on concrete sub-piers or caissons. Sub-piers are carried down 75 ft. below datum, the base of each pier being belled out. Joint between walls of pit and floor slab was double keyed and surface was roughened. Concrete in pit walls was placed in vertical stages varying from 4 ft. at bottom to 8 ft. at top. Each stage was concreted without interruption, and joints between stages were double keyed and roughened. Torpedo sand and gravel were used as fine and coarse aggregate. For sub-piers and south machinery pit, standard portland cement was used. For north pit, which was first to be concreted, Super cement was used, concrete being placed during cold weather. South pier was concreted during warmer weather. Proportions in north pit were 1:2.5:3.5, with 6 gals. water per sack of cement. For south pit and all sub-piers, mix was 1:1.7:3.2, with 6 gals. water per sack of cement. Slump in all cases was 4 in. Concrete mixing plants for pits were separate installations, because presence of river navigation made transportation across stream inadvisable. From mixing plant for north pit which included mixer, aggregate measuring hoppers for volume measurement of aggregate and water control equipment, concrete was delivered into a hopper and wheeled in buggies over runways.—C. BACHMANN

BUILDINGS

Light-concrete for construction of 400 dwelling houses in Berlin-Zehlendorf (Germany). WEISS. *Zement* (Germany), Nov. 13, 1930, V. 19, No. 46, p. 1090-2.—Construction was carried out with a concrete containing gravel and Rhenish pumice stones as aggregates. Heat insulating properties make this an ideal material for small dwelling buildings. Interesting and economic methods were used for putting up formwork and distributing of concrete with a minimum of laborers. About 455 cu. yds. of concrete were placed daily. Outside of buildings was finished with white cement.—A. E. BEITLICH

Five scattered hospital buildings concreted from one plant. *Concrete*, Dec., 1930, V. 37, No. 6, p. 17-18.—On government hospital project at Northport, Long Island, N. Y., comprising six reinforced concrete buildings, concrete for five buildings was mixed at centrally located plant equipped with batchers, water-measuring device and 10-S mixer, located directly between two of larger buildings. For two buildings concrete was distributed by buggies, direct from hopper alongside main hoist tower, and above mixing plant. Hoisting tower and long chute sloped about 35 deg. with horizontal was used for building farther away. Plastic consistency was maintained by addition of gallon of admixture to each 2-sack batch. Mixing time was 1 min., 10 sec. Proportions specified and used for columns and footings and for floor slabs, beams and girders, were 1:2:4 with 6½ gal. of water per sack of cement. For roadway and plain concrete work, mix was 1:2½:5 with 7½ gal. of water per sack of cement. Mixing plant was set low as practicable and trucks hauling aggregate ran up incline built with excavated material and dumped directly into bins through open side near top of mixing plant.—C. BACHMANN

Construction of new city hall in Ruestringen (Germany). HANS KUBALL. *Bauingenieur* (Germany), May 16, 1930, V. 11, No. 20, p. 349-52.—Structure consists of three parts, separated by expansion joints; a 15-story tower structure and two side buildings. Underground conditions and presence of aggressive agents in ground water made foundation on wooden piles necessary. About 1000 piles, 12 in. and 14 in. in diameter and 40 ft. long, were driven. Great care was taken in protecting concrete against action of water. Very rich cement mortar (1:2) with addition of waterproofing compounds was used for cementing a protecting layer of bricks. Detailed description is given

of several interesting floor constructions. High early strength cement was used for tower structure and normal portland cement for construction of side buildings.—A. E. BEITLICH

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, Nov., 1930, V. 37, No. 5, p. 27-29.—Details of form work around steel beams and in intervening floor panels of building having steel frame encased in concrete are shown in illustration. The entire floor form work is supported on short cross pieces 3 in. by 4 in. about 27 in. apart, held in place against the beam bottom by wire passed over steel beam and tightened by twisting above top flange of beam. Wires pass through form work at edges of beam bottom, with beam sides set against them and supported on cross-pieces. Form work for floor construction is assembled by tacking beam bottom plank to cross-pieces, then wiring this assembly to steel beams after small concrete blocks are inserted between beam bottom plank and lower flange of steel beam. Width of beam bottom must be 4 in. more than width of bottom flange of steel beam, leaving 2 in. space for concrete to pass on each side of flange. Next the lower boards of beam sides are set in place, then 2-in. planks that serve as blocking for floor joists are set on cross-pieces, and lower boards of beam sides tacked lightly against them. Floor form panels are placed and upper boards of beam sides are set and tacked lightly to ends of a few joists. Floor panels have previously been assembled by nailing ⅞-in. boards to joists. If enough men and hoisting equipment are available, a floor form panel may be made up to full area of floor panel. If lighter form units are necessary, several smaller form panels may be used instead of a large one. The ⅞-in. boards of floor panel project over beam sides. Removal of this form will be made easier if floor boards adjacent to beam are omitted from assembled panel, and set in place and lightly tacked after floor panel is set. When the form work is removed, floor panel can be lowered as soon as plank blocking is taken away. To remove floor form construction: Shore up one edge of floor form panel by temporary frame; cut wires at beam where floor panel is shored, and remove cross-pieces and beam bottom. Remove 2-in. blocking and lower boards of beam sides. Let down edge of floor panel by lowering temporary shoring frame, and remove panel and upper boards of beam sides. Ends of wires protruding from concrete may be cut off flush with the concrete unless needed to support lath and plaster. Form work for lens sidewalks consists essentially of boxes supported on ledges, beam sides being slightly battered to facilitate removal. Form work for window sill consists essentially of yokes shaped like inverted "U." Tin strap at upper right-hand corner is to provide partial hinge action so yoke can be released. Form for parapet coping involves keeping true alignment for long stretches of wall. Use continuous liners in combination with cleats and spreaders all of 3 in. by 4 in. material. Staggering liners with respect to those on opposite side of coping helps maintain alignment.—C. BACHMANN

DAMS

Construction of the locks in the river Main upstream Aschaffenburg (Germany). FRIEDEL. *Zement* (Germany), Oct. 23, 1930, V. 19, No. 43, p. 1015-8.—Progress is reported of construction of 13 locks in river Main which enable navigation and serve for power production. Each lock has three openings which are 114.8 ft. wide. Ship locks are 984.3 ft. long and 39.7 ft. wide allowing passage of 3 or 4 ships at a time. On opposite side of river are located the hydro power stations. Two turbines in each station transform energy of 4,600 cu. ft. of water per second to 21 millions K. W. hours. For each station will be consumed about 80 to 90,000 cu. yd. of concrete. Locks at Obernau (Germany) are completed. Details of its dimensions and operation of gates are given. Locks at Kleinwallstadt, Klingenberg-Trennfurt and Kleinheubach are still under construction and work at Freudenberg was just started. Gradual development of these jobs is clearly illustrated.—A. E. BEITLICH

The power stations of the Lake Schluchsee. ADOLF EISENLOHR. *Bautechnik* (Germany), April 18, 1930, V. 8, No. 17, p. 259-63.—Water, which runs from Lake Schluchsee (Germany) and several other points of southern part of Black Forest (Germany) to river Rhine is utilized in three hydro power stations in Haeusern, Witznau and Waldshut. Difference between levels of Schluchsee and Rhine is 2950 ft. Meteorologic observations during 30 year period showed high average of rainfall in this region, 39.4 to 70.9 in. Steps between power stations are 659.5, 918.6 and 360.9 ft. Upper station in Haeusern is now under construction. Several small waters are collected and led to Lake Schluchsee through concrete pipe which is 5.6 ft. in diameter. Dam of gravity type, which is 108.3 ft. high and crest of which is 872.7 ft. long, dams water to level 95.1 ft. higher than original one, forming a lake of 1.9 sq. miles surface with a capacity of 141 million cu. yds. of water. Overflow is located in middle of dam. Dam is straight and has triangular cross-section. Concrete pressure line between dam and power station shows very interesting design. Inlet is located about 46 ft. below lake level. Pipe 3.7 miles long leads in nearly straight line to power station in Haeusern and has circular cross-section with inner diameter of 13.4 ft. Two gates are provided for regulation of water stream. Further description is given of construction of foundation of power house with its 4 turbines. Water basin for second hydro power station is formed by dam 495.4 ft. long, which has very favorable location. It is slightly curved and of same cross-section as first structure. Its pressure line is 1.7 miles long and 16.4 ft. in diameter. Arrangement of sites of construction, transportation and preparation of structural materials is described and illustrated.—A. E. BEITLICH

Blasting a pre-cast dam into place. (See ENGINEERING DESIGN—DAMS.)

MISCELLANEOUS

Construction cranes. "Baukrane." R. CAJAR. 1930, R. Oldenbourg, Munich and Berlin (Germany), 275 p., 354 illustrations, R. M. 18.00. Reviewed in *Z. Oesterr. Ing. Arch. Ver.* (Austria), Oct. 10, 1930, V. 82, No. 41-42, p. 367.—Book is comprehensive treatise on subject of construction cranes. Besides detailed description of different kinds of cranes, their operation and power consumption, several calculations are given for steel construction of such cranes and steel ropes.—A. E. BEITLICH

Methods of obtaining watertight concrete. WILLI SERKIN. *Betonwerk* (Germany), June 1, 1930, V. 18, No. 30.—Watertight concrete is dependent on non-absorbent aggregate, dense mortar, the sand grains of which are so graded to produce the least voids. Methods of attaining this grading are analyzed. The cement should be further made water repellent with an admixture prepared for this purpose.—H. FRAUENFELDER

Lectures on reinforced concrete construction. "Vorlesungen uber Eisenbeton." E. PROBST. 1929, Julius Springer, Berlin, V. 2, 2nd edition, 540 pp., 61 illustrations, RM. 31.50. Reviewed in *Bauingenieur* (Germany), Jan. 24, 1930, V. 11, No. 4, p. 69.—In four main chapters following subjects are discussed: reinforced concrete construction of superstructures, bridges, marine structures and miscellaneous structures. It deals mostly with practical application of different construction methods for large halls, silos, ceilings, foundations, different types of concrete bridges, sewers, pressure pipes, locks, dams, breakwaters, caissons, wells, poles and chimneys. V. 1, which appeared in 1923 illustrates theoretical side of subject.—A. E. BEITLICH

Concrete piles. M. J. MCCARTHY. *Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930. Abstracted from *Conc. Constr. Eng.* (England), Nov., 1930, V. 25, No. 11, p. 628-32.—Methods of

casting concrete piles are given for both piles that are cast in molds before being driven into the ground and for piles cast in place. Advantages of piles cast in place over the pre-cast piles are given. Pre-cast piles are most suitable for jetties, piers, and wharves. Five methods are given for casting piles in place and the methods are compared.—JOSEPH MARIN

Coast protection. *Conc. Building Conc. Products* (England), Oct., 1930, V. 5, No. 10, p. 139.—For protection of a rocky coast with concrete, a 12 in. thickness of 1:2:4 concrete is recommended, reinforced with ½-in. dia. bars at 12 in. centers each way. The bars should project 9 in. into the rock and 9 in. into the concrete, with both ends hooked.—JOHN E. ADAMS

The concrete pump, a new concreting method. HEIDORN. *Der Bauingenieur* (Germany), May 30, 1930, V. 11, No. 22, p. 381-4.—Experiences with a new concrete pump during construction of "German House" in Flensburg (Germany) and several other construction jobs are described. Concrete was pumped 88.6 ft. high. Output was 350 cu. ft. per hr. Control tests showed, that concrete delivered from pump has great uniformity in composition and strength. Special pipe construction facilitates mounting and cleaning. Transportation and operation costs are very low.—A. E. BEITLICH

New York subway construction—IV. *Eng. News Record*, Nov. 20, 1930, V. 105, No. 21, p. 796-800.—Precast-concrete blocks are being used for lining shield-driven subway tunnels from Prospect Park to Prospect Ave. and Terrace Place in Brooklyn. The use of precast-block or monolithic concrete, at option of contractor, was specified as an alternate to cast-iron segments to determine whether a lining could be secured that would be cheaper than, but as desirable as, cast-iron lining for shield driven tunnels. On tangents the lining consists of rings of 10 standard blocks, each block 6 ft. 1 in. long on chord of outside arc, 18 in. thick and 30 in. wide, forming a tube 16 ft. 9 in. inside diameter and 19 ft. 9 in. outside diameter. Each block contains 0.8 cu. yd. of concrete and weighs 3,200 lb. Curve alignment is taken care of by tapered rings, narrowing by 3.4 in., 1⅜ in., or 2¾ in., in precisely the same manner as cast-iron taper rings. Using these three different taper rings in combination with standard rings in proper proportion gives any desired curvature of tunnel. —D. E. LARSON

New locks in Ijmuiden (Holland). ANTON VAN RINSUM. *Die Bautechnik* (Germany), May 9, 1930, V. 8, No. 20, p. 305-8.—Structure is one of greatest European ship locks. Its inner dimensions are: 1312.4 ft. long, 164.1 ft. wide and 49.2 ft. deep. Ground water level was lowered 26.2 ft. and excavation was carried 42.7 ft. below normal sea water level. Further depth of 85.3 ft. was reached by using Larssen steel sheet piling 88 ft. long driven 3 ft. in hard layer of clay. Foundation rests on concrete piles made at site of construction. A total of 6100 piles were driven. Bottom slab of lock consumed 14,130 cu. ft. of concrete and was placed in 18 hours without interruption. About 31,780 cu. ft. of concrete were placed in 48 hrs. for each side wall. Concrete mixture was very rich and made with an addition of trass as protection against sea water action. Dune sand and blast furnace slag cement without trass addition were used for part of structure. Lock heads consumed about 2½ million cu. ft. concrete of which 250,000 cu. ft. were used for concrete piles. Concrete was poured with plastic consistency, 820 lbs. of cement for 35 cu. ft. of concrete. Concrete mixer furnished 1,060 cu. ft. concrete in one hour. One distribution tower of 255 ft. high was erected.—A. E. BEITLICH

Reinforced concrete construction. Part I. Raw materials and their production. "Der Eisenbetonbau. Teil I. Rohstoffe und Herstellung." O. HENKEL. 1929, H. A. Ludwig Degener, Leipzig (Germany), 112 p., 136 illustrations, R. M. 4.00. Reviewed in *Z. Oesterr. Ing. Arch. Ver.* (Austria), Oct. 24, 1930, V. 82, No. 43-44, p. 379.—Ways and methods of reinforced

concrete investigations and research in modern institutes for testing structural materials are clearly illustrated. Concrete construction control is discussed in all details. Engines, mixers, means of transportation, storage and preparation of aggregates and cement are described.—A. E. BEITLICH

Novel shield and hexagonal concrete liner blocks features of tunnel job. *Eng. News Record*, Nov. 13, 1930, V. 105, No. 20, p. 771-773.—An electrical conduit tunnel, 4 ft. in diameter and 100 ft. long, involving the use of a new design of interlocking hexagonal precast concrete lining blocks and a shield having several innovations, has just been driven for the Philadelphia Electric Co., in North Philadelphia. Tunnel has an inside diameter of 4 ft. and block lining thickness of 5 in. One complete ring of lining contains 18 blocks, but because of their hexagonal shape 9 alternate segments are always half a block width ahead of the other nine. This feature was an essential part of shield operation. Half of the 18 shield jacks were bearing against blocks in place, while the alternate nine, retracted, were extended one at a time under low pressure to hold blocks of next half ring in place as they were set. All of segments are uniform, no key blocks being used. The blocks are elongated octahedrons, 5 in. thick (radial to center line of tunnel), 8 in. wide (longitudinal to center line of tunnel), formed by two hexagonal faces, the outer face curved to form outer diameter of tunnel, and inner face composed of three flat planes. They are fully interlocking, 3 of contact faces having grooves $\frac{9}{16}$ in. deep and other 3 having tongues $\frac{1}{2}$ in. high. Cost of this type of construction is said to compare favorably with open-cut construction up to 10 ft. deep and to be cheaper for greater depths.—D. E. LARSON

Movable distribution arrangements for cast concrete. V. MENG. *Zement* (Germany), Nov. 13, 1930, V. 19, No. 46, p. 1094-6.—Modern concrete distributor which was used during construction of double locks at Kembs i. E. (France) of ship channel between Kehl and Basle (Switzerland), includes one tower located at each side of excavation and movable on 4 tracks. Height of each tower is 196.8 ft. and it can distribute concrete over a radius of 230 ft. Widths of tracks are 6.6, 59.1 and 6.6 ft. Total weight without ballast is 275 tons; traveling speed is 8.2 ft. per minute. At base of tower are two concrete mixers of $1\frac{3}{4}$ cu. yd. capacity, automatic measuring devices for water and concrete silo for 5 cu. yd. of concrete. Elevator delivers material to second silo on tower from which it is further distributed by means of pipes. Each tower can place approximately 78 cu. yd. concrete per hour, but this figure can easily be increased by installing $2\frac{1}{2}$ cu. yd. mixers.—A. E. BEITLICH

Construction of a new breakwater in the harbour of Stralsund (Germany). SEETZEN. *Bautechnik* (Germany), June 27, 1930, V. 8, No. 28, p. 435-8.—Article describes construction of three breakwaters, which are 1263.1, 1780.5 and 367.5 ft. long and replace old wooden pile structures. Greater part of new breakwaters is reinforced concrete construction. Great difficulties were encountered in finding sound underground for foundations.—A. E. BEITLICH

Ready-mixed concrete sold on strength basis at low unit cost. *Concrete*, Dec., 1930, V. 37, No. 6, p. 21-22.—Mechanical installations wherever feasible make low unit costs possible for Brooklyn plant. Cement company barge transports bulk cement in railway freight cars. Five-in. pump conveys cement to three main storage bins, from which series of screw conveyors carry cement horizontally to receiving hopper of vertical bucket elevator. Latter raises cement to 600 bbl., 2-compartment service bin, for standard and special cements, located near mixer. Self-cleaning, 300 ton aggregate bin above mixer is filled by stiff-leg derrick from nearby barges. Ten by 10-ft. hopper fitted with spout and mounted on turntable is located on top of aggregate bin. Proportioning equipment attached to aggregate bin includes quadruple, 16,000 lb. weighing batcher having four radial gates for bin and four-beam scale of

multiple type. Other attachments are 3,000-lb. weighing batcher for cement and 250-gal. water-cement ratio measuring tank. Proportioning units are adequate for 3-yd. batch. Controls and scales arranged so one man can measure cement, water, both aggregates, and discharge materials into mixer and operate mixer from operating platform. Mixer is timed for 1½ minute intervals between batches. Time required for discharge and charging is 15 seconds. Delivery trucks have 5 cu. yd. capacity, full load being made up by 3 yd. and 2 yd. batches. Field testing equipment is installed on mixer floor. Commercial laboratory representative checks control of strength, takes cylinders for tests, makes changes due to moisture variations. Concrete is usually sold on strength basis; proportions generally are 1:2:4; 1:2½:5; 1:3:6. Forty-five trucks with agitator bodies deliver up to 800 cu. yd. in 9-hour day. Aggregate bins are lined with cylinder heaters using steam under pressure of 25 to 30 lbs. Operating force includes 8 men.—C. BACHMANN

Ship locks of the Shannon power station in Ireland. FRIEDRICH WIENER. *Die Bautechnik* (Germany), May 30, 1930, V. 8, No. 23, p. 335-8.—Lock consists of two sections founded on solid rocks. Two side walls of upper section rest on 3-ft. thick reinforced concrete slab made of special cement and basalt aggregates. Bottom of lower section lies 47.4 ft. below that of upper section. Construction of it was similar. Box shaped gates of reinforced concrete are operated from bridges, spanning lock. General description of construction details and of operation of lock is given. (cf. M. Enzweiler, *Die Bautechnik* (Germany), June, 1930, V. 8, No. 25, p. 359-70, *J. of the Amer. Concr. Inst.*, Oct., 1930, V. 2, No. 2, Abstr. Sect. p. 50).—A. E. BEITLICH

New drainage pumping stations of Emscher Corporation in Essen (Germany). ALEXANDER RAMSHORN. *Bautechnik* (Germany), May 9 and 23, 1930, V. 8, No. 20-22, p. 299-303, 330-2.—Extended drainage system with great pumping station in Karnap drains area in mining district subject to slow sinking. Site of pumping station was chosen where greatest sinking is expected to take place to insure sufficient gradient at all times. Station consists of underground pumping room and engine house. Underground structure is reinforced concrete frame construction carefully made tight against ground water. Frame is a twin-cell box frame of Ehler type. Walls are divided into strips 3 ft. wide, reinforced according to load. Ground below building can sink over one third of its length without endangering structure. Excavation was made inside steel sheet pilings. Greatest care was taken in making a very dense, watertight concrete. Aggregates were carefully examined and improved by sieving and proportioning according to Fuller curve. Blast furnace slag cement was used for preparation of a stiff, plastic concrete. Excavation was first provided with layer of cinders on which was placed 6-in. layer of concrete. Brick walls were erected on all sides with a ¼-in. layer of insulating material. Then reinforced concrete floor slab and walls were erected. Description includes details of arrangement of suction and pressure pipes, engine house and adjacent building. Construction of second pumping station in Sterkrade (Germany), built in 1929, of similar design is described.—A. E. BEITLICH

Remarkable concrete and reinforced concrete structures in the steel works of Friedrich Krupp A. G. in Essen-Borbeck (Germany) FRANZ SCHLUETER. *Zement* (Germany), Oct. 2-9, 1930, V. 19, No. 40-41, p. 943-8, 968-70.—Outstanding concrete and reinforced concrete structures of greatest German steel works are described. (1) Quay at south side of main harbor has total length of 755 ft. and is made of concrete mixed 1 part blast furnace slag cement and 6 parts of gravel with an addition of trass. Precautions were taken for raising quay 6 ft., since underground is expected to sink slowly on account of undermining. Two travelling cranes for unloading boats run on top of quay and on reinforced concrete wall 781 ft. long. Forms for this wall consisted of one movable section suspended from wooden travelling crane on which was

concrete distribution equipment. (2) Storage bins for iron ore and limestone consist of one structure 361 ft. long with total capacity of 13,000 cu. yds. It is divided into 24 sections, which are 18.0 ft. long for ores and 22.1 ft. long for limestone. Partition walls are of reinforced concrete. Floors have slope of 40 and 45 degrees. (3) Foundation of one blast furnace consists of reinforced concrete slab, 55.8 by 59.1 ft. and 11.5 ft. thick. It carries a cylindrical reinforced concrete structure, inner core of which is filled with lean concrete mixture, and 4 main columns of blast furnace. (4) Chimney 230 ft. high and 9.8 ft. inner diameter at top was constructed of hollow concrete bricks, made at site of construction and provided with vertical and circular reinforcements. At height of 105 ft. above floor is located water tank around stack, with capacity of 211,000 gallons. (5) Boiler and power house are made exclusively of concrete. Furthermore, following concrete structures are described: water pipe 850 ft. long and foundation of a gas tank of 39,000 cu. yd. capacity.—A. E. BEITLICH

Bonding Concrete. *Contr. J.* (England), Oct. 1, 1930, V. 103, No. 2677, p. 1033.—Evils attendant on careless bonding of new concrete to old are not always appreciated. Shrinkage stress resistance is reduced and a poorly constructed joint may become susceptible to moisture percolation. Disintegration from frost, penetration of chemicals in solution and disfiguring efflorescence may result. Surface of well matured concrete becomes very hard and unless crust is removed by chipping, brushing with wire brush, rinsing with clean water, and a neat cement slurry added, satisfactory bond will not be formed. After slurry application, cement mortar of similar composition to that embodied in new concrete, and of plastic consistency, should be applied and followed immediately by new concrete, which should be well worked against the joint. In laboratory, excellent results have been obtained by following slurry with cement mortar, composed of two parts cement to one part sand, by weight, and following this by mortar, 2 parts sand and 1 part cement by weight. When fresh concrete is placed against this differential shrinkage is reduced to a minimum. Emphasis is laid on need for removing laitance film and layer of porous concrete immediately below it. Forms should if possible be filled to a point slightly above required height, so that poorer material may be struck off before concrete stiffens up, and within less than four hours. Too wet mixes should be avoided and when depositing under water, concrete should not be allowed to fall through water. Hacking of surface for bonding should only be done when concrete is very hard. In this case similar mortar to that in the new concrete mix should be applied in a ½ in. layer, and new concrete worked up against it. (c. f. Bonding new concrete to old. Norman Davey. *Building Research Bul. No. 9*, England).—JOHN E. ADAMS

Monolithic reinforced concrete chimneys. OTTO HOFFMANN. *Zement* (Germany), Aug. 28, 1930, V. 19, No. 35, p. 828-34.—Historical review illustrates development of construction methods for tall chimneys. Concrete form bricks with inlaid vertical and ring reinforcements were used in former years. Very little was known about stresses, in tall chimneys due to uneven heating, nor about heat permeability and radiation. Theoretical and practical experiments led to a rapid development in monolithic construction methods with adjustable, sliding forms. Investigations by Moersch, Graf, Doering, Knoblauch, Koch and Kleinlogel are cited and discussed. Use of high early strength cement made rapid concreting possible. Several outstanding reinforced concrete chimney structures, are described which show clearly progress made during last years. Chimney, 196.85 ft. high, in Obercassel (Germany), shows application of sliding forms in their early stages. System "Heine," used for construction of stack for electro power plant in Finkenheerd (Germany), shows remarkable progress in steel forms. Inner and outer forms consist of steel rings 3 ft. high, supported by scaffold on top of structure.

Structural materials are elevated through interior. Chimney is 361 ft. high and 16.2 ft. in diameter at its top. Two tallest European reinforced concrete chimneys were erected in 1929 for great power plant near Schwandorf in Bavaria (Germany). They are about 460 ft. high with inner top diameters of 24.6 and 18 ft. Structures were completed in 5 months. Stack for chemical plant was erected during severe frost periods with temperatures as low as 13° F. Entire top of structure with scaffolds was protected by closed canvas tent and was heated with steam to about 50° F. Base rests on reinforced concrete foundation slab 45.3 ft. in diameter. Total height of chimney is 262.5 ft. and its diameter at top is 11.8 ft. Thickness of walls ranges from 4.7 to 9.8 in. A very dense concrete made of high early strength blast furnace slag cement was used. Stack is lined with acid resistant bricks, 9.8 in. thick which withstand action of SO^2 containing gases which enter stack at temperature of 392° F. A chimney, which will be 426.5 ft. high when finished, is under construction now. It has a second vertical stack in its interior 131.2 ft. high serving as a flue dust collector.—A. E. BEITLICH

Completion of Moffat Tunnel of Colorado. CLIFFORD ALLEN BETTS. *Proc. Am. Soc. C. E.*, April, 1930, V. 56, No. 4, p. 679-716.—Paper supplements a former paper by R. H. Keays (cf. "Construction Methods on the Moffat Tunnel," *Trans. Am. Soc. C. E.*, 1928, V. 92, p. 63) outlining progress to August 1925. Construction started in 1923 and tunnel was opened to traffic Feb. 26, 1928. Location is 50 mi. west of Denver, at elevation about 9,200 with length 6.2 miles (longest railroad tunnel in America when constructed). It is 2,800 ft. underground at continental divide and involved 750,000 cu. yd. excavation, 16,000,000-ft. board measure timber, 2,500,000-lb. dynamite, 700,000-lb. drill steel, 700 mi. drill holes, 28,000,000-kw.-hr. electrical energy and 25,000,000 man-hours labor. The work includes a large amount of massive concrete and gunited sections. Final net cost $15,470,000. Project involves in addition to standard 16 by 24 ft. railroad tunnel an 8 by 8-ft. pioneer bore from which the excavation at several different headings could proceed from 8 by 8-ft. cross-cuts at about 1,500 ft. intervals. The pioneer bore is to be used as a water tunnel to augment Denver's water supply. West 2.5 mi. was through soft ground and heavy timbering, steel reinforcement, concrete lining, and development of "Lewis Traveling Cantilever Girder" were among important engineering features involved. Surveys and closures, housing facilities, geological and general engineering features are covered in the paper. Concrete mixers and guns for the job cost $26,000. Aggregates were crushed and screened from the tough granite excavated from eastern half of the tunnel. Some stretches of tunnel subject to air slacking were lined with a 1½ 3-in. layer of gunite (1:3 proportions) at about one tenth the cost of timbering. This proved very satisfactory when there was no weight to support. In bad ground very heavy concrete lining was required. Mix was 1:2:3 (water-cement ratio 0.8 to 1.0). Special reground cement was used to give strengths of 2,000 and 4,500 lb. per sq. in. in 48 hours and 7 days respectively. Reinforcement of 30-lb. rails and 1-in. bars was placed between 5½-ton steel sets. Folding wooden forms in 4 ft. sections were used for invert. Then steel forms mounted on a timber jumbo carriage were moved along tracks on finished invert and jacked and bolted into position. Side and top concrete was fed from concrete guns through 8-in. steel pipe to crown of arch. Flowing into place was assisted by workmen with shovels and one-man air hammers used outside the forms. Mixing time was 1½ min.; gun pressure 80 to 110 lb. per sq. in. and a slump of 6 to 7 in. at mixer was necessary to obtain a 4-in. slump in the form. Both stationary and moving gun setups were used and inspection windows were provided in forms. There was segregation in pipe lines if more than 100 ft. long. Concrete thickness ranged from 1 to 5 ft. and a total of 916-lin. ft. of steel lining was buried in 12,000 cu. yd. of concrete including that poured around wooden sets. Provision has been made for placing some added concrete lining each year if necessary. Concrete lining cost $270 per ft. (8.5 cu. yd. at $31.74). A length

of 1,485-ft. of the pioneer water tunnel (62 ft. away) was lined with corrugated pressed steel liner plates which were covered with 4-in. of gunite. This supported loads estimated at 129,000 lb. per lin. ft.—H. J. GILKEY

ROADS AND PAVEMENTS

Maintenance costs. H. K. BISHOP. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—Description of some of the ramifications involved in attempting to compare maintenance costs in different jurisdictions, such as quality of maintenance, accounting methods, equipment, traffic, width and climate.—HIGHWAY RESEARCH BOARD

Repair of pavement settlement. W. H. ROOT. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—A description of a unique method for raising sections of pavement that have settled, by pumping mud through holes in the slabs, with operating and cost data.—HIGHWAY RESEARCH BOARD

Fillers and cushion courses for brick and block pavements. J. S. CRANDELL. *Summaries Papers Reports*, Highway Research Board, Dec., 1930. —The ideal filler to meet the conditions set forth in the report has not yet been found. Some experiments that are under way but not yet ready for study are mentioned.—HIGHWAY RESEARCH BOARD

Recent developments in construction methods and appliances. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—An illustrated discussion showing the latest types of all kinds of equipment peculiar to road construction, and tracing relationships between improved road work, lowered costs and machinery development. Improvements have been brought about principally through (1) changes made necessary by reason of modifications in construction practices, (2) the adaption of existing devices to new uses, and (3) refinements and improvements made primarily for the purpose of increasing operating efficiency. Attention is also called to some further improvements, the need for which is apparent.—HIGHWAY RESEARCH BOARD

Removal of ice from pavements. B. C. TINEY. *Summaries Papers Reports*, Highway Research Board, Dec., 1930.—Attention is called to the need for an investigation to develop information relative to the most effective and economical materials and methods for use in dealing with icy road surfaces.—HIGHWAY RESEARCH BOARD

Economies of grading and paving. A. STELLHORN. *Contr. J.* (England), Oct. 22, 1930, V. 103, No. 2680, p. 1268.—An excess thickness of slab is regarded as evidence of poor engineering supervision since it may represent considerable expense in a large job. It is suggested that screed of finishing machine and sub-grader be set absolutely dependent on each other, a section of grade being subgraded and checked for thickness by running finishing machine in front of mixer and testing grade. The extra work is much less in value than the cost of concrete saved on use of scratch board, which usually causes a grade to be $\frac{1}{8}$ to $\frac{3}{8}$ in. low. Some notes are given on the method of dealing with the excavation, haulage and refilling, rolling and finishing of grades, and then on the paving operations.—JOHN E. ADAMS

Systemization of Vercellese Street in the Province of Milano. ERIK SILVA. *Le Strade* (Italy), March, 1930, p. 79-84.—Development of provincial streets radiating from city of Milano is most important part of a general plan of street systemization which has been progressing since 1927, and includes not only placing of new road surfaces, but also of rearrangement of the gas, electric, sewer, telephone, power and car lines. Vercelles St., an important artery is 82 ft. wide constructed, after much study, with a central safety zone

23 ft., two thoroughfares of 19.7 ft. and two side walks of 9.8 ft. wide. The street sections are given a slope of 2 per cent to the right side for drainage and to give easier driving. The base of the road is concrete and the surface asphalt. On a section of 2390 sq. yd. "Walterite," a penetration type of bituminous surface, was used. Every effort was made to plan the road so that subsequent breaking through to change piping, etc., would not be necessary. The cost was about $24.50 per sq. yd. of which $10.70 was for paving.—C. G. CLAIR AND M. N. CLAIR

Modern concrete pavements. E. K. SMITH. *Canadian Eng.*, Sept. 9, 1930, V. 59, No. 11, p. 309.—Concrete pavements in cities built 36 years ago are still giving good service. In the United States 50,000,000 sq. yd. of concrete pavements are built yearly. Materials are tested before use and proper mixture is determined by laboratory studies. Some methods which have resulted in economy with increase in quality are proportioning aggregates by weight, central mixing plants with delivery to job in some type of agitator body, greater attention to limitation of water content of batches, rigid steel side forms which assist in obtaining a smooth surface free from waves or inequalities, improved finishing machines which permit the use of batches of low water content, greater attention to curing by means of "ponding" or the application of some surface coating which prevents evaporation, and proper placing of expansion joints properly protected by a mastic filler.—G. M. WILLIAMS

Seattle's concrete pavements cured with continuous sprinkler. H. F. FAULKNER. *Concrete*, Dec., 1930, V. 37, No. 6, p. 19-20.—City's specifications require that as soon as pavement can be sprinkled without injury to fresh concrete, it shall be covered with burlap sheets two feet wider than pavement, the contractor supplying sufficient burlap to cover day's run, with 2 ft. lap for each sheet. Covering must be kept continuously wet and maintained in place until system of continuous sprinklers is installed following morning. Sprinklers shall be operated day and night without interruption for 10 days. Perfected sprinkler head throws very fine spray or mist, and when screwed into tees on 1¼-in. pipeline about every 20 ft. will continuously water 25-ft. pavement. Automatic, intermittent valve control in hydrant lead supplying line of sprinklers is also permitted. Device may be adjusted to give on-and-off periods of sprinkling, saving 75 per cent of water. To overcome strong wind, line of heads is tipped toward wind.—C. BACHMANN

A section of pavement with rigid reinforcement. ERIK SILVA. *Le Strade* (Italy), Feb., 1930, p. 58-61.—Aurelio Saffi Street in Milano was paved in 1910 with compressed asphalt and has stood up well under traffic except for portion occupied by two car tracks. Street was repaired by excluding traffic and placing a rigid reinforced concrete base 12 in. thick under the rails. Rails are attached to short sections of cross beams spaced a foot or two apart and embedded in the concrete. Machine cut blocks of porphyry quartz with bituminous mortar joints were used for wearing surface. A sand cushion is used between concrete base and blocks. Street was opened to traffic after one month. The economics of this type of pavement relative to the less rigid types is discussed.—C. G. CLAIR AND M. N. CLAIR

Patching concrete roads. GEREKE. *Betonstrasse* (Germany), July, 1930, V. 5, No. 6.—Tests of repairing concrete roads on a test street in Braunschweig showed good results. One part (by volume) cement, 1.6 parts sharp sand, 2.4 parts granite chips, ¼ in. to 1 in., mixed with 1 part of Sika No. 3 and 1.5 parts water were used. Holes were first washed with a mix of one part sand and one part cement. Material was applied in 6 to 7 minutes. Tests were made after 45 hours and showed different results for different kinds of cement used. It was estimated that according to test results the patched places could be opened for traffic after 20 to 24 hr.—R. J. DIETRICH

Concrete pavements. *Magazine Tecnico* (Argentina), April, 1930, p. 23.—A general statement of advantages of concrete pavements as found from their use in Argentina. The status of concrete road construction in the Province of Buenos Aires, Argentina, as of September 1929, is given as:

	Sq. Yd.	Cost Per Sq. Yd.
Constructed	125,800	$15.20
In Construction	103,800	11.10
Authorized	210,000	10.70
Projects ready	70,500	13.45
Projects being studied	478,000	11.50

This gives a total of 990,000 square yards at a general average price of $11.90 per sq. yd.—C. G. CLAIR AND M. N. CLAIR

SHOP MANUFACTURE

Observations on cast stone and the cast stone industry. *Betonwerk*, (Germany), April 6, 1930, V. 18, No. 21.—The proper name for this product is discussed. "Betonwerkstein" appears most popular. The product and its qualifications are described.—H. FRAUENFELDER

Concrete structural members and concrete products in slab construction. R. ROLL. *Beton Eisen* (Germany), Oct. 20, 1930, V. 29, No. 20, p. 370-373.—A brief summary is given of types of precast reinforced concrete load-carrying members and of concrete blocks for use in slab construction. Details of the various systems are shown in the figures. The article presents a view of the present stage of this field in Germany, and companies engaged in the manufacture of these products are listed.—A. A. BRIELMAIER

Profitable manufacture of concrete building units. FRED A. SAGER. *Concrete*, Dec., 1930, V. 37, No. 6, p. 33.—Business of producing and selling concrete products exhibits widest range in methods adopted and used by various concerns engaged in such manufacture. If, by keeping simple records, small plant can change manufacturing schedules from a haphazard to an orderly one with resulting saving, course should be adopted. Fundamentals of good plant design should be known and, if not embodied in present layout, worked into it. Most suitable equipment should be used, though in some cases this may not mean the most efficient machine. This series of articles will analyze business of moderate sized plant and arrive at certain fundamental conclusions as to stock of all types to be carried; plant required; general features of economic plant design and use of plant land; use of simple records to interpret costs; matters of deliveries and contact with customer during delivery; and markets and sales.—C. BACHMANN

Concrete units win way into large buildings. RUSSELL ACKER. *Concrete*, Dec., 1930, V. 37, No. 6, p. 13-16.—In bidding for Fort Wayne, Indiana, masonry market on quality basis, efficient plant having large production volume was found necessary and equipment installed accordingly. Outstanding unit is automatic Anchor junior stripper with tamper, power feeder and power strikeoff, having daily capacity of 2,500 standard size units. Large variety of sizes and quick mold changes are possible. Brick-making attachment added recently produces brick economically with low capital investment. Other units are a Hobbs downface machine under an Anchor floor tamper, with a daily capacity of 500 faced, standard size units, and Anchor tamper over a stripper for making two light-weight concrete roofing slabs at one operation. Masonry units are transported to one of three kilns on cars and steam-cured not less than 12 hours, then moved to yard on transfer track. Four men, one at mixer, one machine man and off-bearer, one all-around man, and one on truck delivery, are employed. Three 1-ton trucks comprise delivery equipment. Calls on architects and other logical prospects met with little success until

samples were left at offices and use of concrete as partition units in large eastern and southern buildings cited. Laboratory tests, building code committee recognition of units, and finally inspections of the plant, with high-grade equipment producing clean-cut block, neatly stored, converted architects. Largest order has been for 100,000 units; others for 15,000 to 20,000.—C. BACHMANN

Concrete cable covers. *Conc. Building Conc. Products* (England), Oct., 1930, V. 5, No. 10, p. 133.—To replace earlier clay product for protection of underground cables, many firms are manufacturing concrete cable covers, which are less easily broken, and which are provided with interlocking devices. A description is given of the latest type of cover, which is 12 in. by 6 in. by 1½ or 2 in. thick and the ends of which are concave and convex. To ensure that these ends shall remain tightly together, covers are provided with loops of galvanized iron wire projecting at each end, the loop at concave end being passed through loop at convex end of adjacent cover, and turned over with the fingers. These wires pass through the cover and act as reinforcement as well as tie, and serve to hold the pieces together in event of their being struck by a pick. Tops of the covers are stamped "electricity." They are composed of clean shingle, and sand from ⅜ in. down mixed with portland cement in the proportions of 1:2:4 and the materials are consolidated in moulds by vibration. Other products such as curb sections and flags are described, with illustrations of plant.—JOHN E. ADAMS

New method of stone preservation. *Betonwerk* (Germany), Oct. 26, 1930, V. 18, No. 43.—It is stated that each kind of stone and cast stone requires special treatment for its preservation. The treatment must not prevent breathing of stone. Experiments have been conducted with Silicic acid dissolved in alcohol or benzol as a surface treatment. This surface treatment hydrolizes slowly and cements grains together. Research being continued.—H. FRAUENFELDER

Tightening the requirements for making pipe C. M. HOWARD, *Concrete Products*, Oct., 1930, V. 39, No. 4, p. 20-21.—In plotting results of a number of sieve analyses it was noticeable that material passing through No. 8 sieve was quite uniform, so this sieve was taken as basis for comparison. Samples were broken on No. 8 screen and percentage of each sample retained was noted. Then the portion passing No. 8 was screened and results plotted. Uniformity of material below screen was quite startling, as was varying percentage of total sample passing. The result is quite obvious. A great deal of variation in material can be eliminated by breaking on No. 8 screen. The aggregate should be controlled by using a maximum of ⅜-in. gravel in all thin-shelled pipe; and it is believed that this is a maximum to be used in any machine-tamped pipe regardless of the thickness, because tightness of compacting is a matter of how large a rock the tamp stick will bed into the dry mix required, and necessity for compactness is as great in one size of pipe as in another. Tamp stick clamp has to be tighter in proportion to effective end area of tamp stick. In large size pipe the stick is larger, friction on stick is set tighter, and there is just that much more chance that tamp stick will have to bed two or three of maximum size aggregate particles in same blow.—E. S. HANSON

MATERIALS

AGGREGATES

Sand and gravel. "Sand und Kies." E. TRUEMPENER. 1930, Kalkverlag, Berlin (Germany), R. M. 4.20. Reviewed in *Zement* (Germany), Nov. 27, 1930, V. 19, No. 48, p. 1146.—Book deals with application of sand and gravel in concrete and other industries and describes properties, which are necessary for such purposes. Modern practice demands higher standards of purity and uniformity. A comprehensive list of references and many illustrations are given.—A. E. BEITLICH

The sand and gravel industry and its problems—Part II. JOHN ZOLLINGER. *Rock Products*, Dec. 20, 1930, V. 33, No. 26, p. 56.—Dredging pump described has special protection by pressure water which protects both runner and shell. This has decreased repair bill two-thirds, based on two years experience. Dredge with portable hull and an 8-in. pump—has hull made of four 8 x 16-ft. pontoons. Four men can easily handle and unload one pontoon. The cabin is in ten sections. The advantages of portable type are lower expenses of transportation and launching and a greater resale value.—EDMUND SHAW

Glacial sand-gravel aggregate found suitable for paving work. L. H. KOENITZER. *Concrete*, Jan., 1931, V. 38, No. 1, p. 29.—Glacial material available in eastern Nebraska and portions of Kansas has maximum size of 1½ in. Most material passes ¾-in. mesh sieve and has fineness modulus of 4.10 to 4.50. Study was made on over 450 9-in. spheres for wear tests, 140 6 by 6 by 35-in. beams for flexure tests, and 500 3 by 6-in. cylinders for compression tests, to determine range of possibilities of the aggregate. Data show that for variable mixes, with constant water-cement ratios and fineness moduli of 3.50 and 4.50, mixes containing 20 per cent passing 28-mesh sieve gave higher strength values than similar mixes containing 10 and 15 per cent passing same sieve; increase in water-cement ratio decreased strength and increased per cent of wear. Mixes giving greatest strength are listed. Total aggregate on six miles of paving showed average modulus of rupture greater than 560 lb. per sq. in. at 10 days; compressive strength of 3800 lb. per sq. in. at 28 days. Total aggregate satisfactory when precautions are taken for expanding and contracting of concrete.—C. BACHMANN

New England quarry plant makes periodical changes. *Rock Products*, Nov. 22, 1930, V. 33, No. 24, p. 41-46.—At beginning of season just passed, the Middlefield, Conn., plant of the Connecticut Quarries Co. changed from steam to electric power and from rotary to vibrating screens beside making other improvements reviewed. Power change was made by installing a single 500-h. p. synchronous motor to drive principal crushers and screens. High and uniform power factor resulting has caused a material saving in power cost. Vibrating screens have shown lower power and general maintenance costs and a higher cost for screen fabric, but are found on the whole to be more economical to operate than rotary screens. Quarry face of hard trap rock is 1,500 ft. long and from 80 ft. to 190 ft. high. It is worked by a combination of coyote holes and snake holes, each shot being carefully designed on the drawing board. The maximum burden allowed is 60 ft. Loads as great as 54,000 lb. of 40 per cent powder have been shot. The recovery is estimated to run between 5 and 5½ tons of rock per lb. of powder and practically no secondary shooting is required. Haulage is by motor truck.—EDMUND SHAW

A year's operating experience with a new crushing plant. NELSON SEVERINGHAUS. *Rock Products*, Sept. 27, 1930, V. 33, No. 20, p. 33-38.—The superintendent of Consolidated Quarries Corp., Lithonia, Ga., tells what a year's experience with a new plant has taught. Blast hole drilling originally

was 18 ft. spacing with 20 ft. burden. The rock broke clean from the face but fragmentation was poor requiring too much expensive block-holing. The burden was reduced to 16 ft. for the second shot with much better fragmentation. Drilling is now being tried with 5⅝-in. holes set 18 x 20 ft. The charge will build up faster in this size hole and less stemming will be required. It cost 79¢ to break the average oversize piece by mudcapping and 34¢ by blockholing. As the quarry is in a locality where the same rock is cut for building stone and paving blocks, the method of breaking by short holes and wedges was tried. Cost was about same as for blockholing but larger pieces were left to be handled by shovel. Reversable control on crusher motor has saved cleaning out crusher after shut down. Author believes lowering crusher speed from 170 to 125 r. p. m. would reduce peak load, lessen wear on bearings and still give sufficient capacity. Due to accumulation of fines in bins and stockpiles, recleaning vibrating screens have been put in over loading bins. Some washed sand is being produced from screenings by the use of an Anaconda type rising current classifier.—EDMUND SHAW

Effect of flat and elongated pieces in crushed stone used as an aggregate in concrete pavements. A. T. GOLDBECK. *Crushed Stone J.*, May, 1930, V. 6, No. 5, p. 2-11.—This investigation was designed to answer two questions: (1) Are flat pieces actually harmful in finishing of concrete pavements? (2) What effect do flat pieces have on strength of concrete? Flat fragments were defined as those whose length exceeds five times the least average dimension. Only larger size flat pieces, those retained on a 1¼-in. screen, were considered harmful. Slabs 3 ft. wide, 6 ft. long and 6 in. thick were made of 1:2:3½ concrete with 0, 5, 10, and 15 per cent of flat pieces, and of 1:2:4 concrete with 0, 5, and 10 per cent of flat pieces. Two slabs of 1:2:4 concrete were made in which gradation of stone was varied. Best index of difficulty of finishing was considered appearance of concrete after each successive passage of steel screed, and finally, after use of wood float. Slabs were broken into beams which were tested at age of 28 days for modulus of rupture. Following conclusions were drawn: (1) Presence of up to 10 per cent of flat pieces in stone has no noticeable effect on difficulty of finishing 1:2:4 concrete, provided same stone with flat pieces removed produces concrete which may be finished without difficulty. (2) The presence of flat pieces only slightly increases percentage of voids in stone and requires no change in water-ratio to produce concrete of same consistency as obtained with stone having zero per cent of flat pieces. (3) Changes in gradation of stone have a far greater effect on percentage of voids and mortar voids ratio than flat pieces. (4) The 1:2:3½ mixes were more workable than 1:2:4 mixes. They have much greater factor of safety against variables which may occur in aggregates than 1:2:4 mixes. (5) Flat pieces up to 10 per cent in 1:2:4 mixes and 15 per cent in 1:2:3½ mixes do not decrease strength of concrete. (6) Indications are that flat pieces do not lie in a position such as to cause trouble at surface of a concrete slab.—J. E. GRAY

CEMENT

Investigation of portland cements, rich in ferric oxide—II and III. SHOICHIRO NAGAI AND K. AKIYAMA. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), 1930, V. 33, p. 286-90, 421-8. Reviewed in *Zement* (Germany), Nov. 13, 1930, V. 19, No. 46, p. 1096.—Cements were burned between 2400 and 2460° F. with a ferric oxide content of 7½ to 11 per cent. Raw materials were limestone, puzzolana, copper slag and clay. Mortar strength (1:3) was tested by means of small-piece testing method, invented by author. Compressive strength is lowered when ratio $CaO:SiO_2$ is decreased.—A. E. BEITLICH

Movements of materials in rotary kiln and power consumption. A. NILSSON. *Zement* (Germany), Nov. 20, 1930, V. 19, No. 47, p. 1105.—Mathematical study of movement of materials in rotary kilns. Power consumption

can be calculated by means of formula derived by author. Factors taken into consideration are: weight of materials in kiln, number of revolutions of kiln, changes in weight of mix due to calcination and drying and internal friction of materials. Formula is not considered for use in mill practice.—A. E. BEITLICH

Dusting of portland cement clinker. KATSUZO KOYANAGA. *Rock Products*, Nov. 22, 1930, V. 33, No. 24, p. 66-68.—The opinion of Dyckerhoff is quoted, that dusting of clinker comes with a change of dicalcium silicate from the β to the γ modification which is accompanied with about 10 per cent increase in volume. The author then describes his investigation of dusting clinker which was made through the accidental inclusion of a piece of flint stone, probably, with a raw meal of known composition. Microscopic examination showed the original clinker to be largely Alit. The dusting portion of clinker was mainly Belit. It was much higher in silica and lower in lime than original clinker. Tests were made by fusing pure reagents to $CaO.SiO_2$, 2 $CaO.SiO_2$, and 3 $CaO.SiO_2$. The melt of 2 $CaO.SiO_2$ broke into white powder. Tests were then made with two kinds of raw meal, one high and the other low in sesquioxide. Silica, some of which was taken from such bricks as are used in kiln linings, was added and rods were molded which were melted in an oxy-acetylene flame, allowed to drop in a heated crucible and then cooled. Six series of these melted clinkers were plotted on a ternary diagram. The line connecting the dusting points was nearly straight through the points of 2 $CaO.SiO_2$ mixtures. When the dusting clinkers were tabulated dusting was shown to occur through a wide range of chemical composition. But the contents of lime and silica can never be higher than 64.92 per cent CaO or 35.08 per cent SiO_2. The higher the content of sesquioxide lower the content of lime and silica and the longer time it will take to begin dusting. It is thought that dusting more often occurs with silica than aluminous brick lining.—EDMUND SHAW

Investigations on operation and efficiency of air separators. II. P. ROSIN AND E. RAMMLER. *Zement* (Germany), Oct. 16, 23, 30, Nov. 6, 1930, V. 19, No. 42, 43, 44 and 45, p. 984-8, 1011-4, 1035-8, 1060-1.—An illustrative case is worked to analyze process of grinding in tube mill with an air separator. Tests were conducted with coal. Amount of feed was varied while all other conditions were kept constant. Samples were taken at various places and their fineness determined. Influence of rate of feed and number of revolutions of air separator fan on (1) fineness of end product, (2) number of circulations of feed, (3) load of elevator and actual load of mill, (4) efficiency of air separator and (5) power consumption were carefully examined. Results of tests were used for expression of encountered conditions by mathematical formulas. Use of these formulas and their application to mill practice are especially emphasized. Reference is made to work by Rosin and Rammler, *Zement* (Germany), June 27, July 18, Aug. 1 and 8, 1929, V. 18, No. 26, 29, 31 and 32; A. B. Helbig, *Ibid*, Jan. 9, 1930, V. 19, No. 2, p. 25-8, *J. Am. Concr. Inst.*, April, 1930, V. 1, No. 6, Abstr. Sect. p. 69.—A. E. BEITLICH

Reply to the article by Alton J. Blank on ignition losses. KATSUZO KOYANAGI. *Rock Products*, Dec. 20, 1930, V. 33, No. 26, p. 67.—Discussing Mr. Blank's view that the harder clinker is burned the less moisture it will absorb, the author says moisture absorbed in storage is function of two factors, (1) quantity of moisture in atmosphere and (2) hardness of clinker. But a higher burned clinker may absorb more moisture than a soft burned clinker if it is stored in atmosphere with more moisture. Author's experience is quite opposite to Blank's statement that he has never known strength qualities of cement to be bettered by storage whether in humid or dry atmosphere. Hourly samples of cement are taken at outlet of mills and packers and mean strength found. Mean strength after one month of storage is always a little higher than that of same fresh ground cement. Many tests on effects of storage have shown

that storage of moderate length is effective in increasing strength of cement, or at least it is not harmful.—EDMUND SHAW

Investigation of portland cement and its constituents by means of measurements of vapor pressure. F. KRAUSS AND G. JOERNS. *Zement* (Germany), Nov. 6, 1930, V. 19, No. 45, p. 1054-5.—New method is proposed, which enables investigator to study formation of hydrates and to observe kind of hydrates which are present. Nature of process (if it is formation of crystals or colloids) and amount of water which is taken up can be studied. Two different ways are worked out, one is determination under isothermal conditions and one under isobar conditions. Latter way is superior for study of portland cement. Substance is exposed to vacuum at certain temperatures. Vapor pressure will always be constant when true hydrate is present until this is decomposed, which fact will set off state of equilibrium. Micro-tension-eudiometer by Krauss and Schriever and its operation is described.—A. E. BEITLICH

Reaction of carbon dioxide and acetic acid on portland cement. HANS TH. BUCHERER AND F. W. MEIER. *Zement* (Germany), Nov. 27, 1930, V. 19, No. 48, p. 1134-8.—Suspensions of cement in water were treated with carbon dioxide and amounts of lime and silica, which went into solution, were determined. Intention of investigators was to remove lime as completely as possible without attacking silica, but it was found that besides calcium bicarbonate considerable silica was dissolved. Acetic acid was then used in 1 per cent solution in addition to carbon dioxide with specially prepared indicator. Carbon dioxide was introduced under constant stirring and calculated amount of 1 per cent acetic acid was added drop by drop avoiding any excess acid. About 24 per cent of total silica was dissolved. Further tests were carried out with acetic acid alone and phenolphthalein as indicator. Results of tests are plotted in curves and given in tables. Comparisons were made between reactions of great number of different cements (portland and high alumina) with acetic acid and their strength properties. It was found that cements with low compressive strength show steep titration curves with only small consumption of acetic acid while cement with similar chemical composition but high compressive strength consume more acid during titration and have flat curves.—A. E. BEITLICH

Researches on the rotary kiln in cement manufacture. Part VI. GEOFFREY MARTIN. *Rock Products*, Oct. 25, 1930, V. 33, No. 22, p. 43-44.—Heat radiated from kiln walls in decarbonating zone is 43,338 S B. t. u. in 1 hr., where S equals the surface in feet. To make 1 lb. of clinker, decomposing 1.1905 lb. $CaCO_3$ at 805° C., 811.92 B. t. u. are required. Heating 1-lb. material from 805° C. to 100° C. requires 148.7 B. t. u. The total heat per lb. of clinker which is required in the decarbonating zone is therefore 148.7 plus 811.9 = 960.6 B. t. u. And for one ton of 2240 lb. it is 2.152×10^6 B. t. u. The coal required is shown to be $2240 \frac{M}{y}$ lb. per hr. which evolves $28.23 \times 10^6 \frac{M}{y}$ B. t. u. per hr. Unbalanced residue of heat must be counterbalanced by same amount of heat radiated from kiln walls, because the temperature of walls must steadily increase as heat plays upon them until they radiate back as much heat as they receive. Equating the heat radiated away against the free heat from the coal gives: $43358\ S = M \times 10^7 \left(\frac{28.23}{y} - 2.152\right)$ which calculates to $S = M \left(\frac{651}{y} - 49.63\right)$ If y is assumed to be 3 then S equals 167.4 M. A table is appended giving the surface in the decarbonating zone required for outputs of 1 to 20 tons per hr., based on this value of y. This formula is said to be new. The length of the decarbonating zone is figured from

surface and diameter. It has been previously shown that $d = 2.98\sqrt{M}$ and as $S = \pi\, dL$ then $L = 17.88\sqrt{M}$. A table gives the required lengths of decarbonating zones for outputs of 1 to 45 tons per hr. and diameters from 3 ft. to 20 ft.—EDMUND SHAW

Researches on the rotary kiln in cement manufacture. Part VII. GEOFFREY MARTIN. *Rock Products*, Nov. 8, 1930, V. 33, No. 23, p. 36.—Theoretical deductions of sizes of preheating and drying zones of kilns are difficult. Empirical experiment has shown following formulas to give approximately correct results for wet process kilns, slurry to contain 40 per cent moisture, where L is the length of the kiln: Cooler end, 2/21 L; Clinkering zone, 4/21 L; Expulsion zone, 5/21 L; Preheating zone, 3/21 L; Drying zone, 7/21 L. The relation of length L to diameter d is worked out to: $L = 25\ (d - 1.5) + 0.2\ (d - 1.5)^2$. For dry process kilns the relation is: $L = 20\ (d - 1.5) + 0.2\ (d - 1.5)^2$. d is stated to be diameter of iron shell in the decarbonating and drying zones. Where diameters vary up and down the kiln d must be taken as the average diameter. Commenting on this article, the Editor, *Rock Products* says: "Apparently about 260 to 365 ft. is the proper length for the usual American wet process kiln, 11 ft. 3 in. diameter of the steel shell. For the dry process the kiln should be only about 50 ft. shorter, which would seem to prove most of our dry kilns too short."—EDMUND SHAW

Researches on the rotary kiln in cement manufacture. Part VIII. GEOFFREY MARTIN. *Rock Products*, Nov. 22, 1930, V. 33, No. 24, p. 47-49.—Theory of expulsion of CO_2 from lime and magnesian carbonates is discussed with an explanation of disassociation pressures and Johnstone's table. It is concluded that in a rotary cement kiln CO_2 begins to evolve at 805° C. at the point where the raw material enters the calcining zone. But as it enters the sintering zone the temperature at which it begins to evolve CO_2 is reduced to 748° C. Practically this means that evolution of CO_2 is almost infinitely slow at these temperatures at the points in the kiln mentioned but as the temperature of the raw material increases beyond these limits the rapidity of expulsion rapidly increases. At 900° C. the bulk of the CO_2 has probably been expelled, last traces going off probably at 1100° C. The time factor is of great importance. Years would be required at 805° C. at start of calcining zone whereas a few minutes would suffice if raw material temperature were brought to 900° C. It would be very desirable to determine minimum time of passage through furnace at temperatures from 800° C. to 1100° C. to arrive at time constant for different temperatures. Influence of speed of kiln gases over surface of material should also be investigated. Having collected such data one would be in a position to design a kiln on scientific lines. At present kilns are designed on rules founded on experience for lack of chemical and physical data. An appendix to this part gives a digest of references to disassociation of carbonates published in literature relating to cement.—EDMUND SHAW

Indirect determination of lime in cement and similar materials with standard sodium oxalate (Sorensen). A. HEISER. *Zement* (Germany), Dec. 4, 1930, V. 19, No. 49, p. 1154-5.—Titrometric method for determination of lime is described. Latter is precipitated with a known excess of sodium oxalate which in turn is back-titrated with solution of potassium permanganate of known concentration. Sodium oxalate of highest purity is used for this purpose. Potassium permanganate solution is boiled and filtered before standardization. Procedure of determination is as follows: Filtrate from R_2O_3 precipitate (of 1.0000 g. sample) is heated near boiling temperature, made acid with strong HCl and then 1.9832 g. sodium oxalate is added. After boiling for about 5 minutes more HCl is added until precipitate is dissolved. Calcium oxalate is then precipitated by adding slowly strong ammonia to slight excess. After settling, solution is filtered into 500 cc. measuring flask and carefully washed with hot water. After cooling flask is filled with water

to mark and 100 cc. are withdrawn with a pipette. To this latter portion are added 400 cc. water, 20 cc. strong sulphuric acid and 20 cc. manganese sulphate solution. After heating to 158° F. it is titrated with 1/10 normal potassium permanganate solution. Volume corrections are necessary when temperature in laboratory changes frequently. Method is simple and gives good results.—A. E. BEITLICH

Marquette has new tow boat. *Rock Products*, Dec. 6, 1930, V. 33, No. 5, p. 68.—The "William Dickinson," 125 ft. long, 26-ft. beam and 7-ft. molded depth, new tow boat of Marquette Cement Manufacturing Co., tows four self-unloading barges, each of 5000 bbl. capacity, with Fuller-Kinyon pumps for pumping cement ashore. It is powered with two Atlas-Diesel engines of 350 h. p. at 225 r. p. m., connected to propellers by air operated clutches that slip with an overload. A new hydro-pneumatic control of clutches has been designed by the builders. The propellers, 6 ft. dia., 63-in. pitch, are solid semi-steel. Double cast iron rudders are used foreward and aft of each propeller. A hydro-pneumatic steering gear operates either set independently. There is no wheel, steering being by levers which are synchronized with helm angles. Hull is all steel. Stern is straight sided and flat topped to faciliate the easy entrance and discharge of water to the propellers.—EDMUND SHAW

Seven 120 ft. cement kilns replaced by one 305 ft. in length. *Pit and Quarry*, Dec. 17, 1930, V. 21, No. 6, p. 25-28.—Plant of the Wolverine Portland Cement Co., at Quincy, Mich., in operation since 1899 has been altered numerous times and, with the changes made in 1930, is up to date. Raw material is marl, excavated by a clamshell-bucket dredge and pumped into large wooden barges which are towed from the small chain of lakes, through a barge canal, to the dock at the main plant. Dredging is precluded during about three months each winter. The marl is pumped from barges, by a return-air system, into steel storage tanks of a combined capacity of 540 cu. yd. Samples are taken and clay is added as marl flows to pug-mill. From pug-mill the mixture goes first to a vat and thence to tube-mills. Slurry then flows to another vat and thence to tanks of 90 cu. yd. each. A long screw conveyor takes slurry to the kiln building where it is elevated and fed to kiln which is 305 ft. long by 10 ft. in diam. and is driven by a 100-h. p. motor at one revolution in 58 sec. Gases from kiln are withdrawn by a 10-ft. fan. Coal is dried, pulverized and pumped pneumatically into steel bin whence it is fed to the air stream furnished by a 4-ft. fan, into the firing end of the kiln. Electric recording pyrometer registers the temperature of the exhaust gases. Clinker drops into a pit and thence by two drag-chain conveyors to a pan conveyor which leads to storage. Drag-chains can move the clinker to a cooler which discharges to storage. A monorail hoist with a 1-cu. yd. clamshell bucket reclaims the clinker and discharges it to a scale where gypsum is added. The material is then elevated to feed nine 30-in. mills. Final grinding is in two tube-mills. Cement goes to a 14-ft. air separator and the coarse fraction returns to tube-mills. Finished product is taken by screw conveyors and elevators to a bin storage.—A. J. HOSKIN

Strength properties of cements during 1930. (See PROPERTIES OF CONCRETE.)

MISCELLANEOUS

Some of the problems of coloring concrete. GEORGE RICE. *Concrete Products*, Dec., 1930, V. 39, No. 6, p. 16-17.—This article takes up the coloring of concrete from a scientific standpoint, showing the molecular structure of color used in cement and the manner in which it may be attacked by color-weakening baculli. The author also discusses methods for preventing the weakening of colors, as well as the interaction of one color upon another.—E. S. HANSON

Studies on fundamental synthesis of calcium aluminates and their hydration—Part 7. SHOICHIRO NAGAI AND RYUICHI NAITO. *Kogyo Kwagaku Zasshi, J. Soc. Chem. Ind.* (Japan), 1930, V. 33, Supplemental Binding, No. 8, p. 315-8B. Reviewed in *Zement* (Germany), Dec. 11, 1930, V. 19, No. 50, p. 1192.—Heat tests with Jaeneckeit showed that this compound consists at 2642° F. of 1 tricalcium aluminate, 2 dicalcium silicate and 1 CaO. Between 2732° and 2822° F. combination of CaO and dicalcium silicate to tricalcium silicate takes place. Eutectic mixtures of β-$2CaO.SiO_2$ and $5CaO.3Al_2O_3$ were obtained by heating to 2462° F. This mixture has relatively high strength properties. Similar tests were conducted with gehlenit.—A. E. BEITLICH

Hydrates of calcium sulfate. F. KRAUSS AND G. JÖRNS. *Tonind. Ztg.* (Germany), Nov. 24 and 27, 1930, V. 54, No. 94, p. 1467-8, No. 95, p. 1483-4.—The great variability of results reported in literature for hydrates of calcium sulfate occurs because of sensitiveness of these compounds to changes in grain size and to experimental conditions. Previous history is also important. The work of Linck and Jung establishing the zeolitic character of the hemihydrate is confirmed. To prepare pure hemihydrate start with freshly precipitated dihydrate, heat for a short time at its decomposition temperature, cool quickly where two forms are in equilibrium to reduce the production of anhydrite. The transformation took place at 59° C. and at a vapor pressure of 7 mm. in the absence of air.—F. O. ANDEREGG

Action of gypsum, swelling and hydration processes. F. TIPPMANN. *Zement* (Germany), Oct. 30, Nov. 6, 13, 20, 1930, V. 19, No. 44-47, p. 1030-5, 1056-60, 1080-6, 1106-12.—Opinions about effect of gypsum and anhydrite on setting properties of cement differ widely. Berger, Meade and Budnikoff have in general no objection to use of anhydrite as portland cement retarder, while Platzmann and Hart do not favor its use. Comprehensive tests were made to clear up this problem. Four different retarders: (1) raw gypsum rock of high purity, (2) natural pure anhydrite, (3) semihydrate ($CaSO_4.1/2H_2O$), produced from gypsum rock by heating for several hours at 311° F. and (4) stucco, regenerated dihydrate from waste of clay industry. Grinding tests were carried out with a well burned clinker in great laboratory ball mill in lots of about 70 lbs. over 5 hour periods. Additions of retarding agents ranged from 1 to 6 per cent. Obtained products were tested for fineness, setting time, 3-, 7-, 28-day compressive and tensile strength after combination storage, volume constancy, Le Chatelier test and SO_3 content. Additional tests were made with 2.5 per cent raw gypsum rock and 4.5 per cent anhydrite for 16 hours. Temperatures in mill during grinding process were carefully determined. It was found that anhydrite shows less retarding effect on clinker than the other modifications with water of crystallization. Slow setting products were prepared with 2 per cent raw gypsum, 1 per cent semihydrate, 2 per cent stucco and 4 to 5 per cent anhydrite. Constancy of volume was not affected by these high additions. Changes in SO_3 content of samples seem to indicate that a partial thermal dissociation takes place, caused by heat in mill. Regenerated dihydrate is not affected and needs higher temperatures. Author discusses opinions of numerous investigators (Biehl, Platzmann, Killig, Kuhl, Probst, Dorsch, Schmidt and Haehnle) and compares their findings with his own results. He claims that no calcium sulfoaluminate is formed when cement and water react together. This compound was prepared synthetically by treating white portland cement of the Medusa Portland Cement Co. (Ohio), with saturated solution of gypsum. Reactions of calcium sulfoaluminate and semihydrate with water and progress of crystallization with gypsum solutions of different concentrations were studied under microscope. Investigation includes studies of formation of colloidal gels in gypsum solution in connection with swelling tests. Special built apparatus allows microscopic observation of a stirred mixture of cement or cement compounds in gypsum solutions or lime water. Two phases of reaction could be observed: (1) electrolyte causes agglomeration of fine

particles without destroying their structure (apparent swelling process) and (2) true swelling process of solid residue and formation of new substances (silicate needles and aluminate plates) takes place; gypsum has little influence on this phase of reaction, while concentration of calcium hydroxide has great effect. Retarding effect of gypsum seems to be due to fact that a weak gypsum solution retards speed of solution of lime causing slower formation of hydration products. Silicate needles and an abundance of a transparant gelatinous substance which contains silica and lime (probably a pseudo-crystalline or liquid-crystalline modification of a calcium silicate) were found between set cement plates under water storage. Transformation of calcium hydroxide crystals from a colloidal to a crystalline form could be observed under microscope. Synthetic calcium aluminate hydrates were prepared and their optical properties determined. Finally solution phenomena of cement in sugar solutions of different concentrations and formation of crystal phases were examined. Thirty-nine references, 28 microphotographs, 11 graphs and several illustrations are given.—A. E. BEITLICH

PROPERTIES OF CONCRETE

The chemistry of the resistance of concrete to corrosion. WILLI SERKIN. *Betonwerk* (Germany), June 15, 1930, V. 18, No. 24, p. 334.—A discussion of action of soluble portion of cement in connection with insoluble aggregates, and of the influence of water on lime content of cement. Methods now in vogue to protect concrete by integral methods, changing the soluble portions into insoluble, surface and impregnation materials are fully discussed and described. It is cited that as yet no universal method of protecting concrete has been discovered.—H. FRAUENFELDER

Crystal Springs dam in California, 40 years old concrete still watertight. *Zement* (Germany), Oct. 23, 1930, V. 19, No. 43, p. 1022.—Data of inspection of Crystal Springs dam, which is still in perfect condition after a 40 year period, indicate that this condition is due to an extraordinarily careful construction control, use of perfect aggregates and systematic treatment of finished concrete.—A. E. BEITLICH

Overheating of aggregates found detrimental to concrete. WILLIAM H. BACHELDER. *Eng. News Record*, Dec. 18, 1930, V. 105, No. 25, p. 973.—In cold weather it is often necessary to heat concrete aggregates. Some specifications require that concrete when placed shall have temperature of from 70 to 140° F. This temperature has some effect on chemical reaction that takes place when cement sets. It has been assumed that effect of higher temperatures on resulting concrete is beneficial. A series of tests in Minnesota highway department laboratory showed that temperatures above 70° F. should not be used if the full development of strength inherent to concrete is to be obtained. Concrete placed at 130° F. loses approximately 20 per cent of its strength.—D. E. LARSON

Artificial influencing of strength of concrete—Part 3. C. R. PLATZMANN. *Zement* (Germany), Nov. 27, 1930, V. 19, No. 48, p. 1139-41.—Several surface hardeners for concrete are discussed. Special consideration is given to "Metalicron," a product made by Master Builders in Cleveland, Ohio. Properties of this material were carefully studied and abrasion of concrete specimens treated in different manners were measured. Photographs show corrosive influence of lactic acid, sugar solutions and acids from fats and oils. Microphotograph of Metalicron is given. A surprisingly high increase in strength was found of specimens stored in a solution containing 8 per cent sodium sulphate and 2 per cent magnesium sulphate.—A. E. BEITLICH

Retempered mortar. *Concrete Constr. Eng.* (England), Dec., 1930, V. 25, No. 12, p. 696.—Results are given of tests made at the Building Research Station to determine effect on strength of mortar of remixing cement mortars up to periods of 30 to 45 minutes after mixing and after initial set has taken place. The rate of hardening of cement and consistency of mix are important factors in deciding final result. For slow hardening portland cement it may be possible to regauge cement mortar for periods up to possibly 4 hr. without loss in strength, while for rapid-hardening and aluminous cements there is risk of loss in strength occurring due to retempering. Two series of tests were carried out at Building Research Station. One series for normal slow hardening portland cement and the other for rapid hardening portland cement. Values are given of strengths for varying times of remixing. The general conclusion made was that the process of retempering cement mortar and concrete cannot be recommended.—JOSEPH MARIN

Control of concrete construction. "Die Baukontrolle in Betonbau." BREBERA. 1929, Eduard Gregrasin, Prague (Czecho-Slovak Republic). Reviewed in *Bautechnik* (Germany), Sept. 19, 1930, V. 8, No. 41, p. 636.—Tentative directions for production of concrete are derived under consideration of all experiences in recent years with big concrete construction jobs. After emphasizing necessity of construction control, author discusses factors which influence quality and strength of concrete. Ball-test by Heinzel for determination of setting time is described and also a method for testing binding properties of cement, found by determining flexural strength of 10-in. long mortar prisms. Special consideration is given to chapters on aggregates, methods for determination of impurities, practical gradations and proportioning according to Abrams fineness modulus. Mixing water and influence of natural water content of aggregates on strength are considered. Final chapter discusses equipment and apparatus for perfect concrete mixing.—A. E. BEITLICH

Mixing proportions not only factor affecting concrete strength. ALBERT MERCIOT. *Constructeur de Ciment Armé*, Oct., 1930, No. 133, p. 217-219.—Somewhat out-of-date to American readers are arguments collected here in favor of field control of concrete. Concrete strength should not be conditioned by mixing proportions, relative proportions of sand and gravel, quantity of mixing water, or method of working concrete. It should be sufficient to simply specify that after a certain lapse of time concrete on the job should show a resistance to rupture, which, in accordance with factor of safety desired, corresponds to working stresses assumed in the design. This will give great freedom to contractor in choice of his materials and methods. Uniformity of concrete will be secured on the job. Scientific control on the job will eliminate complaints of fraud. Already there exist in France companies which will give this type of service on reinforced concrete construction work.—M. A. CORBIN

Strength properties of cements during 1930. ALEXANDER HASCH AND LEOPOLD RISTER. *Osterr. Bauzeitung* (Austria), Nov. 15, 1930, V. 6, No. 46, p. 752.—Compressive and tensile strength data of cements tested during 1930 by Austrian Institute for Testing Materials in Vienna are tabulated. Such cements are ordinary portland cement, high early strength portland cement, Kuhl cement and several foreign brands of fused high alumina cements. Additional durability tests were carried out by storing specimens in various aggressive solutions—sulphuric acid (5 per cent), magnesium sulphate (5 per cent), ammonium nitrate (5 per cent), sodium nitrate (1 per cent) and saturated gypsum solution. Solutions were renewed every 2 weeks.—A. E. BEITLICH

Effect of shrinkage in large concrete dams. M. A. RENAUD. *Annales Ponts Chaussees* (France), March-April, 1930, V. 1, No. 2, p. 144-179.—Fissures produced by shrinkage of concrete in dams are important in their extent. Study of how fissures were produced can only be made after failure has taken

place, and then there is doubt as to what actually took place in the interior. Engineers in charge of the Saint-Marc dam observed concrete while dam was in different stages of completion and were thus able to note any fissures that formed and to remove them in time. Dam is of gravity type, 145 ft. high, and contains 97,500 cu. yd. of masonry. Method of construction is explained and stages in placing of concrete indicated by diagrams. Figures illustrate age of concrete of different parts of dam and proportions of aggregates. Extent of fissures was determined by means of colored water and detailed account is given of formation, growth and location of fissures. Extent of fissures is shown by means of diagrams of the cross-section, for different periods of time after the first evidence of a crack was noticed. Main deduction made from observations was that fissures were due to shrinkage of concrete, for construction was not advanced sufficiently for dead load of masonry to produce cracks, nor was temperature sufficiently low to cause fissures. Proposed measures to protect against formation of new fissures, and method of repairing dam in which fissures are already formed are outlined. Observations taken on Saint-Marc dam point out necessity of observing dam during its construction for fissures that might form. Fissures in another dam that has been in service for two years were found analogous to those in Saint-Marc dam.—JOSEPH MARIN

Valuation of shrinkage numbers of light-concrete. A. HUMMEL. *Zement* (Germany), Nov. 6, 1930, V. 19, No. 45, p. 1062-6.—Shrinkage of mortar and concrete is due to (1) shrinkage of cement, (2) shrinkage of aggregates, (3) gradation of aggregates and (4) amount of gauging water. Air moisture, temperature conditions and structure of concrete also affect shrinkage. Shrinkage can be reduced by use of lean mixtures with little gauging water; shrinkage process can be retarded by keeping concrete wet until a considerable hardness has been produced. For light-weight concrete, aggregates must have small coefficient of contraction besides heat insulating properties and light weight per cu. ft. Frequently shrinkage numbers of light concrete can be found which are much higher than those of normal concrete. A formula for comparison of shrinkage numbers is derived based on tensile strength, specific shrinkage and modulus of elasticity. Several different concretes are investigated from this point of view.—A. E. BEITLICH

Glacial sand-gravel aggregate found suitable for paving work. (See MATERIALS—AGGREGATES.)

Action of gypsum, swelling and hydration process. (See MATERIALS—MISCELLANEOUS.)

Advantage and versatility of cast stone. (See ARCHITECTURAL DESIGN.)

ENGINEERING DESIGN

BRIDGES

A method of arch design. G. P. MANNING. *Concrete Constr. Eng.* (England), Dec., 1930, V. 25, No. 12, p. 687-689.—Paper deals with "combined moment envelopes," diagrams representing total positive and negative moments for points along the arch. Moments plotted include those due to dead load, live load, crown drop, and temperature. The diagram given is the "envelope" for a specific case. The arch treated is as follows: span, 150 ft., rise 30 ft., open spandrel type with floor and roadway weighing 250 lb. per sq. ft., ribs spaced at 10 ft. centers, live load consists of one standard train including 50 per cent impact, E_c = 2,000,000, I_c = 545,000 in.^{4}, cross section of the rib at the crown 30 in. wide by 48 in. deep with 1.5 per cent steel top and bottom, and a temperature range of + or — 30 degrees. The moments were calculated for two types of profiles and comparison made.—JOSEPH MARIN

BUILDINGS

Large building structure with shock absorption. *Osterr. Bauzeitung* (Austria), Nov. 22, 1930, V. 6, No. 47, p. 767.—New construction principle was used for construction of "Rhenania-Ossag"-house in Berlin (Germany). No direct connection exists between inner structure and outer walls which fact makes this office building shock proof and reduces considerably, vibrations caused by street traffic.—A. E. BEITLICH

Reinforced concrete skeleton structure for an apartment and office building. JOS. HOLZAPFEL. *Zement* (Germany), Nov. 20, 1930, V. 19, No. 47, p. 1114-7.—Design and construction of building at street corner in Munich (Germany) was extremely difficult on account of very unfavorable underground and narrow site of construction. The building is 93.5 ft. long but only 16.4 ft. wide. Construction as reinforced concrete skeleton structure was only possible solution. Details are given of dimensions and reinforcements of structural parts.—A. E. BEITLICH

Cleveland railroads dedicate Union Terminal. Foundations for the Cleveland Union Terminal. C. P. MARSH. *Civil Engineering*, Nov., 1930, V. 1, No. 2, p. 77-88.—This recently completed $88,000,000 project included a 52-story tower supported on foundations extending 204 ft. below rail level. Quantities included 500,000 cu. yd. of concrete and 100,000 tons of steel work. The terminal serves the New York Central, Big Four, and Nickel Plate railroads. Preliminary foundation investigations involved much work of a pioneer nature including library studies, 8,000 linear ft. of test holes, soil analyses, and bearing tests on soil and rock samples and field tests of soil in place. This soil was fine sand containing about 13 per cent clay and 3 tons per sq. ft. was the final pressure allowed for retaining walls and spread footings placed upon it. At 60 or 70 ft. below basements there is hardpan of compact clay mixed with gravel on which a pressure or 7½ tons per sq. ft. was attained. The tower is supported on 16 concrete piers carried to rock for which 100 tons per sq. ft. is allowed. About 1,000 columns are supported on spread footings, the largest of which is 32 by 41 ft. and carries a load of 6,300,000 lb. Tower foundations carry loads from 6,300,000 to 8,900,000 lb. and vary in diameter from 8 ft. 8 in. to 10 ft. 4 in. Minimum pier diameter is 4 ft. and is enlarged only as may be required by limiting stress of 400 lb. per sq. in. in the 1:2:4 concrete (below the spiral) is exceeded. Piers resting on clay have bell bottoms. Foundations cost about $1.25 per cu. ft. and quantities were about 74,000 cu. yd. of concrete and 3,100 tons of reinforcing steel. The paper on foundations outlines the problems and mentions factors such as bearing power, skin friction, subsidence, and cost which entered into their solution.—H. J. GILKEY

Examples of mushroom floors in France. W. CHERRE. *Constructeur de Ciment Armé*, Nov., 1930, No. 134, p. 245-247.—Strasbourg firm "Zublin" has erected numerous mushroom floors in Alsace, including building of the Société Alsacienne de Constructions Méchaniques at Mulhouse. It measures 280 by 82 ft. and comprises 7 mushroom floors. Distance between axes of columns is 23 ft. in longitudinal direction and 26.25 ft. in direction of width. Rectangular slabs measure 23 by 26 ft. and represent considerable spans for reinforced concrete construction, in view of the heavy loading. Loading on ground floor is 1635 lb. per sq. ft. and that of floor above is 410 lb. per sq. ft. Depth of slabs is relatively low, being 20 in. for the ground floor; 10 in. for first floor and 9 in. for floor above. The computations were made in research department of Zublin Co., according to method of Prof. Ritter of the Zurich Polytechnic School. The building was completed in 1926. Another example, built in 1913 by the same company, is warehouse of Société d'expeditions Léon Weiss at Strasbourg. The surface area of the mushroom floors is 86,000

sq. ft.; they are designed to support loads varying from 305 to 450 lb. per sq. ft. The span is 15 ft., the depth of slab varies from 8½ to 9¾ in. Another example is the covering of a reservoir of Dollfus-Mieg Co. at Belfort, built in 1927. The columns are spaced 11.5 ft. in one direction and 11.1 ft. in the other. Depth of slab is about 6 in., designed to withstand a loading of 490 lb. per sq. ft. The author urges further study of this type of construction.—M. A. CORBIN

Continuous slabs reinforced in two directions. W. S. GRAY. *Concrete Constr. Eng.* (England), Dec., 1930, v. 25, No. 12, p. 661-669.—It is often assumed in designing interior panels of uniformly loaded continuous slabs reinforced in two directions that the positive moment is 0.8 times that calculated for a freely-supported panel. There is little justification for this assumption, its derivation being from analogy with beams or slabs reinforced in one direction only. Experience has proved this method is on safe side, but gives no guide to factor of safety. It is well known that method of design of slabs reinforced in two directions by dividing slab into two series of rectangular strips is inaccurate. A more economical design is obtained if reinforcement is designed to resist torsional moments at all points in the slab. Formulae were developed by Dr. H. Marcus which are applicable to mesh-reinforced rectangular slabs with any number of fixed edges and may be adapted to deal with slabs continuous in one or more directions. This method of calculating moments is specified now in German regulations for reinforced concrete. Method of obtaining values of moments is: Slab is assumed divided into two bands of rectangular strips considered as acting independently, and expressions for moments obtained. Assuming equal values of *EI* for the two strips at right angles by equating values for deflections for each strip values of moments can be obtained for each strip in terms of uniform load and length of two strips. These expressions for moments are multiplied by reduction coefficients if corners are restrained, thus allowing for torsional moments and restrained deflection of strip. Curves are plotted showing relation between values of reduction factors and ratios of sides of slab. Ratios of sides of slab of 0.5 to 2.0 were considered. Curves are plotted for different degrees of restraint. Following cases are treated: slab freely supported, fixed on one side, fixed on two opposite sides, fixed on two adjacent sides, fixed on three sides and fixed on four sides. Method is given of obtaining the moments caused by dead load and live load in continuous slabs extending over several panels. Method used is similar to that of obtaining influence lines for continuous frames with unsymmetrical loading, and considers dead load plus live load in alternate panels. Expressions for moments in interior panels can be obtained using the above curves for interior slabs under loading considered fixed on two sides and simply supported on other two. Values of moments due to live load on alternate panels can be similarly obtained from curves for case of panels simply supported. Combining two sets of values given by two loadings moments due to dead plus live load can be obtained. An example explains method of computation for a six-panel continuous frame. Method has advantage over other methods that it is simple. In other solutions of problem effect of continuity is arbitrarily assumed or treatment is too complicated for ordinary office design. The above paper deals only with point load concentrations. —JOSEPH MARIN

DAMS

Hoover dam. ELWOOD MEAD. *Civil Engineering*, Oct., 1930, V. 1, No. 1, p. 3-8.—The paper outlines the Boulder Canyon Project in its larger and in its preliminary aspects. Nevertheless all aspects of a project that includes a 700 ft. concrete dam, a reservoir eight times larger than the Assuan, machinery to develop a million and a quarter horse power, an All-American Canal to irrigate nearly a million acres with an excavation one fourth that of Panama

Canal all at total cost of $165,000,000, should be of interest to readers of the Journal and it is deemed proper that their attention should be called to this treatment which in itself has little to say about many vital concrete features of the project.—H. J. GILKEY

Hydro power station of Rocky River in Connecticut. *Die Bautechnik* (Germany), Aug. 1, 1930, V. 8, No. 33, p. 510-2.—Hydro power development of Rocky River, built by Connecticut Light and Power Co., consists of a water reservoir covering about 8.49 sq. miles. Capacity of lake is 218.5 millions cu. yd. Earth dam rests on concrete wall founded 5 ft. deep on sound rocks. A canal 3400 ft. long on east side of river leads to intake and power station. A generator, producing 30,000 KW. and 2 centrifugal pumps are installed. Plant was designed for a later addition of a second unit.—A. E. BEITLICH

The "cracked" cantilever in dam design. B. F. JAKOBSEN. *Eng. Con.*, Dec., 1930, p. 439-441.—In a brief historical review of the lack of agreement between calculated and actual deflections of dams, the author discusses overlooked factors which tend to materially increase calculated deflections. Shear deformation, yielding of foundation, effect of swelling of upstream side, and time yield of concrete may all combine to produce deformation ten times greater than that found when only bending, calculated from initial modulus of elasticity, is included. This agrees with present-day theory. References given include L. Jorgensen, Frederik Vogt, W. A. Slater, F. R. McMillan, Aarskog, A. H. Fuller and C. C. More. "Cracked" cantilever and the horizontal "hinge" are treated in detail. Mathematical analyses show that ability of "hinge" to produce more favorable stress distribution is quite negligible. Water entering a crack tends to produce tension at bottom of crack whereas compression might have existed had the crack not been present. Shear is greater due to a crack. Calculations of deflections of dams cannot be made with any degree of precision because the great increase in deformation due to plastic yielding is dependent upon the load history of the dam. Temperature changes and water load on the reservoir may affect the deflection of the dam.—N. H. ROY

Water power stations of river Liri in middle Italy. W. VIESER. *Bautechnik* (Germany), Sept. 12, 1930, V. 8, No. 39, p. 580-3.—Favorable water and geological conditions led to construction of several hydro power stations in course of river Liri between Isola del Liri and S. Giovanni Incarico (Italy). Amount of water is practically constant during almost 6 months. Catching area for upper stations is 586.7 sq. miles, for lower stations 1274 sq. miles. Four stations were built in upper part of river. Structures of power plants in middle and lower part of river Liri include gravity dam in Portefiume which forms a water reservoir of 0.58 sq. miles. Dam is 103.4 ft. high, 262.5 ft. long and has volume of 26,160 cu. yds. Downstream side of dam is protected against force of water by sinking of 27 reinforced concrete caissons, each 36 ft. long and 10.3 ft. wide, in 3 rows. Water canal has cross-section of 35.9 sq. yd. and is capable of delivering 109.9 cu. yd. per sec. Power house is 121 by 33 ft. Hydro power station in Ceprano is fed by two water reservoirs connected by canal. Dam in valley of Liri is of gravity type. 283.8 ft. long, 106.6 ft. high and has 103.4 ft. spillway. Reinforced concrete dam in Rio Cancello is 132.8 ft. long and 72.2 ft. high. It has 3 flood gates, each 6.5 ft. square. Connecting canal is lined with reinforced concrete. Water is delivered to power station through cylindrical reinforced concrete pressure pipe 12.5 ft. diameter. Reinforced concrete power house is 196.8 ft. long. Additional information is furnished of construction of stations. Several small dams, weirs and pressure pipe lines in reinforced concrete were built in Fontana Piri, Fontecupa, Serelle and Liri-Fibreno (Italy).—A. E. BEITLICH

MISCELLANEOUS

Calculation practice for reinforced concrete. "Pratique du Calcul

du Beton Armé." G. MAGNEL. 1930, Van Rysselberghe and Rombaut, Paris (France), 3rd part, 360 pp., 12 tables, Frs. 140. Reviewed in *Bautechnik* (Germany), Sept. 19, 1930, V. 8, No. 41, p. 635.—Main subject of book is theory and calculation of concrete and reinforced concrete arches with 2 and 3 hinges. Investigation is carried out for vertical and horizontal loads.—A. E. BEITLICH

Research advances in civil engineering. ALFRED D. FLINN. *Civil Engineering*, Oct., 1930, V. 1, No. 1, p. 14-16.—Attention is called to the value of research as a means for settling differences of opinion and eliminating waste. The varied agencies engaging in research and a great many specific research problems are mentioned. Among those of greatest probable interest which have been sponsored by the Engineering Foundation in recent years are: research on arch dams and dams in general, concrete arches, earth foundations, earthquake stresses, retaining walls, cements, flow of concrete, testing small models, etc. It is pointed out shat all research should begin in the library.—H. J. GILKEY

Reinforced concrete transverse ties for railroads. ROUDOLF. *Bautechnik* (Germany), Aug. 1, 1930, V. 8, No. 33, p. 507-8.—Cracks occur usually in middle of reinforced concrete ties, made of one single piece, no matter how wide they are. Twin ties show greatest damage. Concrete ties are in general made shorter than wooden ties to decrease their weight. New type of ties, system Roudolf, consists of two parts, 8.8 ft. long, connected by center hinge which prevents cracks. Another advantage is great resistance agzinst horizontal stresses. Railroad ties should consist of not more than two parts.—A. E. BEITLICH

Reinforced concrete design simplified. JAMES R. GRIFFITH. *Concrete*, Dec., 1930, V. 37, No. 6, p. 40-41.—Chart O_1 may be used to design tied columns according to the A. C. I. Code. Chart M_1 may be used in designing spirally reinforced columns according to the Joint Committee or the A. C. I. Code. These two charts complete the series. There are now available design charts for beams, slabs, and columns for 2000, 2500, and 3000 lb. concrete.—N. H. ROY

The proposed underground railway system for City of Rome (Italy) and its reinforced concrete structures. JOSEF STELLINGWERFF. *Osterr. Bauzeitung* (Austria), Nov. 22, 1930, V. 6, No. 47, p. 763.—Extensive underground system is projected and designed for Rome, street traffic of which has increased more than five times during last 10 years. Three main lines are 6.73, 3.31 and 4.91 miles long. For tubes and superstructures reinforced concrete will be used, made of high early strength cement. All structures will be proof against aircraft attacks. (cf. *L'industria Italiana del Cemento* (Italy), May, 1930.)—A. E. BEITLICH

Concrete aqueduct irrigates half million acres. GEORGE P. FRENCH. *Concrete*, Dec., 1930, V. 37, No. 6, p. 39.—A reinforced concrete aqueduct across a dried-up river bottom has been built in the neighborhood of Brooks, Alberta, by the Canadian Pacific Railway. The structure consists of two miles of concrete flume, in basin form, 20 ft. wide by 10 ft. deep, supported by steel and concrete trestles. The maximum height of structure is 50 ft. A large inverted siphon of reinforced concrete carries the water under the railway tracks.—N. H. ROY

Elementary calculation of continuous beams. N. RAUBAL. *Osterr. Bauzeitung* (Austria), Nov. 8, 1930, V. 6, No. 45, p. 735-7.—Formulas are derived and examples calculated which illustrate amount and direction of stresses in different kinds of continuous beams under various loads.—A. E. BEITLICH

Structural design of Chicago's subway. *Eng. News Record*, Dec. 11, 1930, V. 105, No. 24, p. 932-933.—Plans for Chicago's subway have been completed to point of showing how structure is to be built. Essentially, project consists of a four-track subway $3^1/_3$ miles long under State St., extending from Eighteenth St. north across the Chicago River to Chicago Ave. and turning west along Chicago Ave. to Franklin St. In general, the subway consists of a roof and walls of concrete jack arches supported by a structural steel frame and floor of reinforced concrete. The latter is reinforced against an upward hydraulic pressure of 90 lb. per sq. ft. The steel bents are spaced 5½ ft. on centers, and in the station areas they are placed at every third bent or 16½ ft. on centers. The river tunnels 1900 ft. long, consist of one double-track and two single-track tubes. The subaqueous section of the tunnels will be steel tubes sunk in place and lined with reinforced concrete, similar to those in New York under the Harlem River and the LaSalle St. tunnel in Chicago.—D. E. Larson

Roads and Pavements

New methods of measuring concussions caused by traffic on roads. Risch. *Betonstrasse* (Germany), Aug., 1930, V. 5, No. 8, p. 194-198.—In general meeting of "Studiengeselishaft fur Automobilstrassenbau" (Institute for the study of the building of automobile streets) the author cited that with increased use of heavy trucks, complaints of damage to buildings and destruction of pipe-lines below the street, claimed to be caused by traffic concussions, have caused desire to measure these concussions to determine truth of these complaints. Instruments used in the past, mostly built according to the principle of the seismometer were not suited. The curves drawn by these instruments were more or less deformed through the vibration of the mass of the instruments. In the "Ambronnschen Beschleunigungs messer" (acceleration meter) is used the Piezoelectricity of closely piled up silicate crystals. The discharge is artificially increased and measured with a galvanometer, actions of which are filmed and the film timed. This instrument is also very easily handled. Several measuring bodies can be placed in different places and directions and the results taken on one film. General principles which have to be taken into consideration in judging results include condition of soil and its ability to conduct concussions.—R. J. Dietrich

Sewers

Concrete sewer design adopted as standard after severe test. *Eng. News Record*, Dec. 11, 1930, V. 105, No. 24, p. 937-938.—The city of Richmond, Va., is to construct about 25,000-lin. ft. of large sewer within the next five years. Studies have led to the development of a horseshoe-type reinforced-concrete section equivalent in capacity to circular pipe with diameters from 60 to 144 in. Salient features of the design are: (1) Vertical and horizontal diameters are practically equal to diameter of an equivalent circular section. (2) Invert acts as no part of structural design except where foundations are soft; thus the washing out of invert does not affect stability of arch and walls. (3) Sheathing of trench can be used as the outside form up to springing line. (4) The design is sufficiently flexible to be adaptable to soils of different bearing capacities. As a final check on design, an 8-ft. section equivalent in size to an 84-in. circle was tested by piling pig iron on a platform resting on the upper quadrant of the arch. Hair cracks developed in center of intrados at both ends when load reached 129,419 lb. The ultimate load was about 153,460 lb.—D. E. Larson

ARCHITECTURAL DESIGN

Reinforced concrete hall designed for clerestory lighting. *Concrete*, Dec., 1930, V. 37, No. 6, p. 34.—Design of Horticultural hall departs somewhat from London building practice in that four tiers of vertical windows rise from the roof arches in step-fashion. Daylight is thus admitted into the large hall by a complete system of clerestory lights. There are several examples of this system on the continent. The building is of reinforced concrete. The foundation rests on clean dry sand.—N. H. ROY

Advantages and versatility of cast stone. WALTER OBST. *Betonwerk* (Germany), Aug. 30, 1930, V. 18, No. 35, p. 487.—Real or imitation, natural or artificial, original or substitute, these are the contrasts encountered in present day enterprises. Many synthetic products today have qualities all their own and do not in the main, imitate the natural product, but in many cases excel. Modern cast stone is such product. It is now used in first-class undertakings, in sculpture and monuments. Cast stone has a structure and texture all its own. It has attained a solid position in the public mind. The outstanding qualities of cast stone are texture, density, color, durability and ease of ornamentation.—H. FRAUENFELDER

Reinforced concrete and aesthetics. E. BLUNCK. *Report of the 33rd main meeting of German Concrete Association*, March 17, 1930, p. 219-35.—Fundamental difference between reinforced concrete and other structural materials is fact that these structures have monolithic character; supporting and supported parts, horizontal and vertical parts are rigidly connected. This construction principle allows greater freedom of shaping. Correct valuation of modern architectural forms is rendered more difficult by traditional opinions, which compare structures with old standards. Uniformity, contrasts, symmetry and rhythm in form and dimensions are most important factors which govern modern aesthetic reinforced concrete structures. Author shows in 15 illustrations selection of recently built structures which are outstanding in their architectural design, and criticises their forms. Such structures are industrial and office buildings, water towers, arch bridges, churches, locks and dwelling houses. Great is number of mistakes and unaesthetic designs, and much fundamental explaining work among contractors has to be done in future.—A. E. BEITLICH

Concrete and reinforced concrete for construction of dwelling houses. MUELLER. *Report of the 33rd main meeting of German Concrete Association*, March 17, 1930, p. 192-219.—Use of concrete for construction of dwelling houses is not very common in Germany on account of its high price and less heat insulating properties than brick walls. Author discusses efforts to overcome these difficulties and describes number of structures recently erected. Concrete with pumice stone as aggregates and air-concrete (large voids) were used for small apartment buildings. More favored is construction with small or larger concrete form bricks, which method eliminates high form costs. Of advantage is shorter time period for drying out of walls. Author describes construction method which uses concrete flat slabs which are especially suited for ceilings forming heat insulating air cells. Reinforced concrete is frequently used for modern apartment house construction allowing greater varieties in architectonical forms. More economic form methods and improved equipment must be developed for further progress.—A. E. BEITLICH

FIELD CONSTRUCTION

BRIDGES

Reinforced concrete bridges of the German railroad concern (Reichsbahn). GEORG MUENZ. *Bautechnik* (Germany), July 11, 1930, V. 8, No. 30,

p. 463-4.—Construction of 3 reinforced concrete arch bridges with spans of 42.6, 49.2 and 82.0 ft. are described and details of their reinforcements are given. Iron portland cement, which gave compressive strength of 7600 lbs. per sq. in. in 28 days, was used in a 1:2½:1½ mix with gravel and broken granite of ¼ to ¾ in. size. Mixing water was kept as low as possible, and concrete was continuously tested during entire construction period.—A. E. BEITLICH

New construction of a viaduct of the Hannover Station in Hamburg (Germany). BLUNCK. *Bautechnik* (Germany), Sept. 5, 26, 1930, V. 8, No. 38-42, p. 563-5, 639-41.—Main railroad line crosses freight tracks in semi-circle with radius of 984.3 ft. Old viaduct structure was 393.7 ft. long and rested on masonry piers. Smoke from engines had done considerable damage to railroad superstructure and piers which fact demanded entire reconstruction of viaduct. Solid roadbed is now constructed, on reinforced concrete two-hinged frame construction, made of 1:4 mix. Most all of old piers were provided with reinforced concrete casing. Road slab consists of transverse I-beams, placed 25.5 in. apart, totally encased in reinforced concrete (1:5). Rods (0.7 in. in diam.) are placed above and below beams spaced 12 in. o. c. Protecting layer of 1-in. neat cement and two layers of asphalt and bitumen insulation were placed. Broken rocks of railroad bed are filled on top and between two reinforced concrete embankments which contain pipes for power and telegraph cables. Drafts for engine smoke and drain pipes were built in road slab. Foundations for frame supports were made of 1:6 mix. Conditions were very unfavorable for storage and preparation of structural materials on account of lack of space. Concrete mixer was located on elevated platform. Cement and aggregates were delivered to mixer from small storage bins by elevator. Small traveling cable crane transported concrete from mixer to workmen. Aggregates consisted of 2.5 parts of gravel and 0.5 parts of broken basalt (0.6 to 1 in.). Entire construction program was carried out without interruption of heavy passenger and freight traffic (over 180 trains per day).—A. E. BEITLICH

Southern Pacific Company's Suisun Bay bridge. W. H. KIRKBRIDE. *Proc. Am. Soc. C. E.*, Aug., 1930, V. 56, No. 6, p. 1307-1318.—Double track railroad bridge replaces two train ferrys on main line of Southern Pacific across Carquinez Straits between Benicia and Port Costa. There is possibility that inactive fault plane crosses site and construction was planned to resist earthquake shock by having centers of gravity of piers as low as possible. Specified 28-day concrete strengths were 2500 and 400 lb. per sq. in. in compression and tension respectively. Steel reinforcement at 30 lb. per cu. yd. of concrete was placed to resist accelerations of 5 ft. per sec. which is twice that of the 1906 San Francisco quake and 1½ times the Japanese quake of 1923. Steel superstructures were planned for similar intensities and were notched into heavy monolithic piers. Swift current, deep water and soft mud bay-bottom called for unique foundation methods. From preliminary octagonal pile platform, 81-ft. diameter steel shells were lowered through water into mud from 15 to 30 ft. Shells were constructed of bolted 10 ft. sections and were extended above water level after which they were filled with sand dredged from river. Caissons were then sunk through sand, inside of shell and properly grounded on rock. A 2-yd. floating concrete plant with 104-ft. tower constituted nucleus of concreting equipment.—H. J. GILKEY

BUILDINGS

Farm storage houses—a market for concrete products—ROBERT H. MOORE. *Concrete Products*, Dec., 1930, V. 39, No. 6, p. 14-15.—This article details the construction of two concrete tile farm storage houses, one with cinders and one with Haydite as aggregate. In first one constructed the original

idea was to build it with double walls of 8 by 8 by 16-in. block with a dead air space between. It was found that a wall of this kind would cost approximately 38¢ per sq. ft. The block manufacturer, however, found that a triple wall could be built of 4 by 8 by 16-in. partition tile for about 36¢ per sq. ft. This would not only give better wall with two air spaces instead of one but would also reduce total wall thickness from 18 in. to 16 in. This method of construction was followed on both buildings.—E. S. HANSON

Development of reinforced concrete construction in Finland and introduction of construction control. OTTO WEYERSTALL. *Report 33rd main meeting German Concrete Association*, March 17, 1930, p. 112-37.—One of first great reinforced concrete structures was saw mill in Lauritsala, a two-story building, 185 ft. long and 100 ft. wide with slab floor construction. Span of beams is about 50 ft. Development was very rapidly until 1911, when first construction control was established. Conditions in Finland are very favorable for reinforced concrete construction on account of its great natural sources for sand and clean aggregates. Of disadvantage are climatic conditions, since cold weather periods predominate. Several modern cement plants furnish excellent cements with high early strength properties. Specifications for testing cement and concrete were issued a few years ago and follow in general lines of German specifications. Great number of structures are described and illustrated showing progress made in recent years.—A. E. BEITLICH

Speedy erection of structural frame proves value of inspection. B. L. MEHANDRU. *Concrete*, Jan., 1931, V. 38, No. 1, p. 21-23.—Erection of Indiana hotel structure demonstrated that co-operative effort between architect, owner and contractor benefits all. Commercial inspection engineers were retained. Building is 12 stories high, reinforced concrete structural frame and floors, 83 by 69 ft. in plan, requiring 3,500 cu. yd. of concrete. Concrete mixing plant including ½-yd. mixer was at rear of building. Concrete was mixed in 2-sack batches yielding average of 11.3 cu. yd. Tubular chute distributed concrete direct from light steel frame hoisting tower. Architect's specifications called for 2,000-lb. concrete in floors, 3,000 lbs. for columns in first five stories and 2,500 lbs. above fifth floor. Both floor and column concrete above fifth floor was designed for 28-day strength of 2,500 lb. per sq. in. Proportions selected yielded 5.65 cu. ft. in place, per sack. Water-cement ratio was 7¾ gal. to the sack. Slump averaged 7½ in. Complete field testing equipment, including molds, was used on job. Cylinders intended for 7-day test were cured at job 4 days, then shipped to laboratory and tested. Twenty-eight day cylinders cured same length of time at job, then shipped to laboratory and cured in moist room. Average strengths were 1,790 and 2,785 lbs. respectively. Although concreting operations were started 9 days behind schedule, roof slab was concreted July 18, 9 days ahead of schedule. Concreting work made ordinary progress in first and second floor construction, second floor having been concreted June 5th. Third floor concrete placed on June 11. Thereafter a floor was concreted every Tuesday and Friday, until the twelfth floor was placed July 12. Run from third to twelfth floor equivalent to story every 2½ days. Actual schedule maintained from third to twelfth floors, inclusive, left 1½ days for moving and framing form work. Time required for concreting floor, 8 hours. Period from Monday morning to Tuesday noon was occupied in getting ready for Tuesday concreting (afternoon and evening). Friday concreting preparations were made on Wednesday and Thursday.—C. BACHMANN

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, Dec., 1930, V. 37, No. 6, p. 35-37.—Considering difficulties of establishing necessary bases on which cost of form work may be estimated in advance, best method is to assume certain average conditions and express required form work for given area in terms of material quantities and hours of labor. Reader may then follow similar methods in figuring his form work problems and arrive at es-

timated cost by applying prevailing unit prices. Greatest variation in cost arises from number of times lumber is used. Comparing 2 and 6-story reinforced concrete building of same ground area, in both cases, floor form panels, beam sides and column forms will be made in sufficient quantity to concrete two floors at a time. On 2-story building forms are used once; on 6-story three times. Cost of material for floor form panels, beam sides, and column forms is as much for 2-story as for 6-story building. Experienced designer makes column sizes in 2-story building alike in both stories, reducing reinforcement in upper columns, and dimensions of roof beams and girders (part below the bottom of the slab) same as floor beams and girders, requiring no patching or altering of form work. Similarly in 6-story building, designer will maintain same column sizes from top to bottom and same beam and girder dimensions below bottom of floor and roof slabs. Following points are guide for estimator: (1) For foundation walls and wall footings of building of moderate ground area, provide sufficient form material for entire area. In building having large ground area, where foundation form work can be erected to keep mixing plant going for about three days, put up only part of form work, moving it second day after concreting is completed. (2) For column footings, make up only enough footing forms so that they can be used four or five times. (3) Forms for columns, for sides of beams and girders, for ordinary floor slabs, for flat-slab floor construction, and walls above grade, should be made up in sufficient quantity for two stories if schedule contemplates one story per week. If two stories per week, make up sufficient forms for three stories. (4) Material for posts, jack frames, braces and other material required to support floor form work must be supplied in sufficient quantity for three stories if schedule calls for one story a week; sufficient for four stories if schedule calls for two stories per week. (5) For beam and girder bottoms which are left in place, along with reshoring timbers and braces, much longer than remaining form work. Quantity of material must be sufficient for four stories if schedule calls for one story per week, and for seven stories if schedule calls for two stories per week. (6) Material for rough structural parts of stairways need not be ordered separately, since rough form lumber can be salvaged from material already used.—C. BACHMANN

DAMS

Salt Springs dam. O. W. PETERSON. *Proc. Am. Soc. C. E.*, Aug., 1930, V. 56, No. 6, p. 1319-1334.—Concrete faced, 328 ft. (above foundation) rock fill dam of Pacific Gas and Electric Co., 70 miles east of Sacramento, Cal., is to impound 130,000 acre ft. to develop all economic available power on Mokelumne River. The main concrete feature is flexible reinforced concrete upper facing 1 ft. thick at top and 3 ft. thick at bottom where it joins the concrete cutoff wall. The average slope of upstream face is 1.3 to 1, top width 15 ft., and bottom 900 ft. along axis of stream bed. Crest length is 900 ft. at elevation of 3959. Of 2,900,000 cu. yd. of rock, 220,000 (7.5 per cent) is derrick placed, 15 ft. thick, upon which the concrete facing is laid. The facing is divided into independent 60-ft. squares. Edges rest on concrete supports poured in grooves left in the rock backing. Two layers of 1-in. round bars at 9 in. o. c. each way reinforce lowest layer and this is gradually reduced to one layer of 1-in. sq. bars 1 ft. o. c. at top. Joints between panels consist of soft copper seals embedded in concrete. Concrete 3,000 lb. at 28 days was designed for maximum density with 5 bags cement per cu. yd. Dam is slightly arched in plan to decrease tension in the concrete facing. Cutoff wall is 6 ft. thick and extends from the base of dam 6 to 20 ft. into good rock. Two inch diameter grout holes 50 ft. deep were spaced 6 ft. apart along bottom of cutoff trench where the dam was over 200 ft. high and near sides at lesser height holes were placed 10 ft. apart and reduced to a minimum depth of 25 ft. at top of dam. To provide a more gradual transition from solid rock to loose fill, the bottom 10-ft. of 15-ft. layer of rock backing is laid up in concrete mortar. This should minimize

tendency of slab to crack at junction of facing and cutoff wall. Spillway solid rock excavation was crushed to 2½ in. maximum size and sand is obtained by passing crushed rock through a cone crusher. Each 60-ft. panel is completed in one continuous operation, forms being moved while pouring is in progress. Concrete is spouted into place by chutes from side dumping, 2 cu. yd. cars hauled by gasoline locomotive.—H. J. GILKEY

Foundation treatment of the Rodriguez dam on the Tijuana River, Mexico. CHARLES P. WILLIAMS. *Proc. Am. Soc. C. E.*, Aug., 1930, V. 56, No. 6, p. 1291-1297.—This dam of Ambursen type now under construction may be statistically summarized as follows: Height 187 ft. above stream bed, 240 ft. above lowest foundation bed-rock. Crest length 2,000 ft. Buttress spacing 22 ft. center to center. Buttress thickness from 19 in. to 66 in. Deck thickness 25 in. to 64½ in. Deck slope (lower face) 1:1. Buttress slope (downstream face) 1:5. Spillway capacity 150,000 sec.-ft. Purpose: To irrigate 5,000 acres and supply domestic water for Tijuana (population 10,000). Drainage area 1,670 sq. mi. Reservoir capacity 110,000 acre-ft. Estimated possible flood 150,000 sec.-ft. Foundation exploration: 9 borings and 52 test pits. Selection of Ambursen type was due to variability in bearing power of foundation rock and fact that dam crossed a fault plane. Most unique foundation feature was the construction of arch to transfer part of four of buttress loads to better rock. Arch was flat below and underside rested directly on soft rock in central portion. Construction permits redistribution of stresses as required if softer rock yields. In the fault zone concrete cutoff wall was poured in open cut 26 to 33 ft. below original rock surface (66 to 72 ft. below stream bed). Below these levels excavation was continued where necessary through shafts left in concrete.—H. J. GILKEY

Experiences from a power plant construction in India. CARL THULIN. *Teknisk Tidskrift* (Sweden), Oct.-Nov., 1930, No. 11-12, p. 129-135 and 145-152.—The Swedish contracting company "Vattenbyggnadsbyrån" in connection with Rendel, Palmer and Trittion of London, has just completed power plant construction on Malakka peninsula for The Perak River Hydro-Electric Power Co., London. The power is to be used for the fabricating of tin. The construction was started in Dec. of the year 1926. The plant was located 6 miles from nearest road in a dense jungle, so road was constructed first, involving excavation of 143,000 cu. yd., and building of several bridges. Over 100,000 tons of material, sand and stone not included, was hauled over this road. As much as 3,500 tons of cement could be transported per month. Trucks with solid tires lasted only half as long as trucks with air tires, so during the later part all new trucks were supplied with air tires. Working force consisted of 110 Europeans and as many as 4,500 laborers. The Chinese were used where certain skill was required, as carpenters, lumber men, etc. Tamiles were used for hauling and Bengali for the heavy work. Lascars were used for work high up in the air. An amount of 20,000 English pounds was spent on different methods of fighting malaria, with such a good result, that the number of sick people averaged only 2 per cent, and for long periods as low as .5 per cent. Contrary to customary practice these precautions were not started before start of construction. To connect two sides of river a suspension bridge with free span of 450 ft. was built. It was designed to carry a train weighing 20 tons. The dam was 1,380 ft. long with a maximum height of 143 ft. Total concrete 143,000 cu. yd., steel 5,700 tons, and forms 1,080,000 sq. ft. Pouring of concrete was very difficult on account of the heat, during the middle of the day—about 140° F. The Insley System with two towers 300 ft. high and 1,000 ft. apart was used. The quality of sand and stone varied, and it was necessary to establish a regular concrete laboratory. Best mixture was found to be: cement 460, coarse sand 140, medium sand 240, fine sand 120, big stone 400, and small stone 400. The forms consisted of 2-in. planks and could not be reused many times, because they seemed to wear out very quickly.

Some kind of white ants that ate up all kinds of soft wood did considerable damage to the forms and other construction of wood. The power plant was opened on June 28, 1930.—ODD ALBERT

Effect of shrinkage in large concrete dams. (See PROPERTIES OF CONCRETE.)

MISCELLANEOUS

Concrete benches reduce maintenance costs in greenhouses. *Concrete*, Jan., 1931, V. 38, No. 1, p. 33.—Concrete soil benches vary from 200 to 400 ft. in length. Bench consists of two curbs, each 16 in. high, 2 in. wide at top and 4 in. wide at bottom. Aisle side is vertical and inside battered. Two curbs for entire length of bench are cast in one operation in special steel forms. No joints are provided, cracks are immaterial. Other benches consist of precast 1-in. reinforced slabs, 12 in. high. Eight ft. lengths are used for sides and 2 ft. 6 in. lengths for ends. Cast iron angles driven into ground at corners hold slabs in position. Slabs made in steel forms using 1:2 mortar, reinforced with ½-in. galvanized mesh. Sixty slabs are required for each bench.—C. BACHMANN

Application of construction methods with sliding forms. KNEES. *Report 33rd. main meeting German Concrete Association*, March 17, 1930, p. 388-409.—After giving a short historical review of development of concrete and reinforced concrete construction methods, author describes various methods for concreting with movable and sliding forms which are in use in several European countries. System Koethenbuerger is based on working in two zones with alternating use of 2 like form sections. It is especially suitable for bin construction. Similar, but superior in many aspects is system Heine, which was developed in United States. Sliding forms became more in favor in Europe during recent years. Greater uniformity of concrete, better construction control, no danger of separation of aggregates or formation of voids, monolithic structure, savings in form work and easy operation are few of advantages mentioned. System MacDonald, also originated in the United States, is described and a number of silo structures and chimneys show its great field of application. In Holland and Hungary, Spindle method enjoys great appreciation, where storage bins of enormous dimensions were built. High early strength cement was used in most every case. Detailed description is given of construction of a cooling tower, elevator tower in Rotterdam (Holland), clinker silos in Neuwied (Germany), oil seed silo in Emmerich, chimney in Kiel and several cement storage silos showing construction progress with above discussed methods. (cf. Knees, *Zement* (Germany), June, 1930, V. 19, No. 24, p. 561-5; Langenbeck, *Ibid*, Feb., 1930, V. 19, No. 6, p. 127-9; Hoffmann, *Ibid*, Aug. 28, 1930, V. 19, No. 35, p. 828-34; *J. Am. Concr. Inst.*, Sept., 1930, V. 2, No. 1, Abstr. Sect., p. 24: *Ibid*, May, 1930, V. 1, No. 7, Abstr. Sect., p. 102.)—A. E. BEITLICH

Reconstruction of quay system in harbor of Memel. NIEBUHR. *Bautechnik* (Germany), Aug. 15, 1930, V. 8, No. 35, p. 527-8.—Increasing traffic during last years in harbor of Memel demanded extension of quay to 1115 ft. and excavation of harbor to a depth of 26.3 ft. and later to 32.8 ft. Underground consists of large granite rocks embedded in very fine gray marl. Steel sheet piling of Larssen type, 51 ft. long, were driven and rigidly connected with existing quay wall. Concrete filling between both was supported by 30 ft. wooden piles. Storage house of reinforced concrete skeleton construction, 262.5 ft. long and foundations for tracks of unloading traveling crane were carried out in record time.—A. E. BEITLICH

Subway station Frankfurter Allee in Berlin (Germany). *Bautechnik* (Germany), Aug. 1, 1930, V. 8, No. 33, p. 508-10—In construction of about 1.1 mile extension of subway railroad system of Berlin, excavating and scaffolding

were carried out under great difficulties to avoid interference with street traffic. Only 33 ft. width of construction site was available for transportation and mixing of raw materials and distribution of concrete. Two mixers with one yd. capacity each handled total of 78,500 cu. yd. of concrete. Floor of tunnel consists of several layers of reinforced concrete (1:5) with a number of protective coatings of asphalt and bitumen. Gravel was especially prepared and did not contain more than 40 per cent passing 4 mesh sieve and left a residue of at least 30 per cent on 8 mesh sieve. Clay content was below 1.5 per cent.—A. E. BEITLICH

Extension of a quay in the harbor of Reiherwerder (Germany). SCHULZE. *Bautechnik* (Germany), July 25, 1930, V. 8, No. 32, p. 487-91.—Quay is 502 ft. long and supported by one row of flat and three rows of round reinforced concrete piles. Total of 989 piles were driven. Mixture of 1100 lb. blast furnace slag cement and 38.84 cu. ft. gravel with a w/c-ratio of 0.50 was used for manufacture of these 50-ft. piles. Pile heads and ends of reinforcements penetrate about 16 in. into main concrete flat slab of quay. Its bottom layer is made of mixture of 666 lb. iron portland cement with 38.84 cu. ft. gravel, while 550 lb. iron portland cement with 42.37 cu. ft. gravel was used for top layer. Joints between flat concrete piling were filled with fabric hose into which a 1:3 cement mortar was poured. Two coatings with Inertol protect concrete against aggressive waters. Foundations of tracks for traveling ore crane rest on vertical reinforced concrete piles placed in distances of 7.2 ft. Iron portland cement was used exclusively for their construction. During entire construction period all structural materials were carefully examined, also compressive strength of concrete and control of mixing operation and distribution. Moisture of aggregates was determined daily to hold w/c-ratio of 0.50 constant. Concrete was mixed in 17 cu. ft. mixer and distributed from movable platform through wooden chutes.—A. E. BEILTICH

Wolfe's Cove Terminals Construction. C. A. LEIGHTON. *Canadian Engineer*, V. 59, No. 21, Nov. 18, 1930, p. 637.—Wolfe's Cove Terminal is being built by Port of Quebec authorities, City of Quebec, in connection with harbor development in the St. Lawrence River. Project covers river frontage of city proper for a distance of two miles, giving total wharfage of 26,000 ft. Construction consists of quay wall for entire length with piers at intervals, which are 2300 ft. long and 435 ft. wide, extending out into river. Wolfe's Cove Terminal consists of 4300 ft. quay wall made up of timber crib to low water supporting superimposed concrete retaining wall. Cribs are 42 ft. high, 62½ ft. wide at bottom and 30 ft. at top. Concrete wall is 26 ft. high, 19 ft. wide at base and 6 ft. wide at top. Concrete was poured one year after building cribs, to allow time for settlement. Concrete face in contact with water up to mean high tide is faced with pre-cast concrete. Pre-cast units are molded in steel forms and cured with live steam. They are placed in the work after two weeks storage. Concrete mix is 1:1½:3. Concrete backing consists of 1:3:5 concrete of which about 50 per cent is placed through tremie. Top of wall above mean high water consists of 1:2:4 concrete. Quantities required are 6500 cu. yd. pre-cast and 50,000 cu. yd. mass. concrete.—G. M. WILLIAMS

Concrete linings for canals—experiences and improvements. S. KURZMANN. *Bautechnik* (Germany), Sept. 5, 1930, V. 8, No. 38, p. 568-71.—Concrete lining has in general 3 conditions to fulfill. It must (1) protect dams and bottom of canals against attacks of water and provide canal with permanent cross-section, (2) decrease roughness of walls and prevent losses of water and (3) protect adjacent land against excessive water infiltration. Observations were made of behavior of canals of several great Bavarian hydro power stations and experiences and improvements are reported. It was found that expansion joints were widened causing some water loss. No great destruction by frost could be found when concrete was properly placed in not too

lean a mixture. Concrete of a 1:0.7:16 cement-trass mixture had partly failed and was replaced. When water level in canal changes frequently, it is possible that great voids are formed underneath lining by washing away of fine material through joints or small leaks. Collapse of concrete walls results. This can be prevented by placing layer of gravel underneath concrete. Special consideration was given to careful treatment of finished concrete. Sand (0 to 0.2 in.) and gravel (0.2 to 1.2 in.)were used in proportion of 2:3 with 300 lbs. cement for 35.3 cu. ft. concrete. Very uniform and dense concrete was obtained. Surface was kept wet for 5 days and covered with ½ in. boards for 2 days. Then a thin suspension of 1 part of cement and 2 parts of very fine sand in much water was poured over concrete to fill fine haircracks and smoothen surface. Additional information is furnished concerning concreting methods, equipment for such jobs, their capacities, power consumption and economy.—A. E. BEITLICH.

ROADS AND PAVEMENTS

Concrete road construction in Argentine. C. E. REYNOLDS. *Concrete Constr. Eng.* (England), Dec., 1930, V. 25, No. 12, p. 691-697.—In describing building of concrete roads in Argentine following topics are treated: The design of roads including the shape of sections used and methods of construction; specifications for materials, including size of ingredients, proportions used, and strength of material; mixing and placing of concrete; method of control of water content by "slump tests"; description of the types of expansion joints used; details of method used in reinforcing concrete.—JOSEPH MARIN

Settled concrete road slabs lifted and leveled by force pump. *Concrete*, Jan., 1931, V. 38, No. 1, p. 27.—Settled concrete slabs are being raised and leveled by pumping mixture of loam, cement and water under them. Pump has chamber in which materials are mixed. Mixture is forced through 2-in. hose. Holes slightly smaller than outside diameter of the hose are bored in the settled pavement on about 6-ft. centers. Hose is forced into one of holes and pump started. Swelling of hose by pressure of mixture holds end fast in hole. Pressure is 5 lbs. or less per sq. in. Mixture hardens in 10 to 12 hours.—C. BACHMANN

SHOP MANUFACTURE

Piece-work vs. day labor. *Concrete Products*, Dec., 1930, V. 30, No. 6, p. 34-35.—This symposium was participated in by 62 readers of whom 14 or 22½ per cent are using the piece-work system in some form or other. Its customary application is only to the men who are operating machines producing block, roofing tile, etc., but occasionally it is applied to other men throughout the plant.—E. S. HANSON

An excellent vibrating apparatus, the table vibrant. JACQUES DUPY. *Rev. materiaux construction trav. publics* (France), Nov., 1930, No. 254, p. 458-9.—An apparatus for mechanical vibration of concrete products requiring small power. The amplitude of vibration can be regulated. Machines of 880 and 4,400 lb. capacity are described.—F. O. ANDEREGG

Gelatine moulds. *Conc. Building Conc. Products* (England), Dec., 1930, V. 5, No. 12, p. 165.—In preparation of the gelatine for casting concrete figures, gelatine sheets should, if new, first be placed for 15 minutes between wet sacking to make them pliable. They should then be heated in a steam jacketted pan until the gelatine is just hot enough to pour, usually after about six hours, gentle heating. All models should first be varnished with shellac varnish and oiled with colza oil. The moulding may be used for about ten times. For reuse it should be washed and cut into 1-in. cubes and melted, without the addition of water, in the pan. New gelatine may be added to freshen up the old.—JOHN E. ADAMS

Operator utilizes excess pea gravel in manufacture of concrete blocks. *Pit and Quarry*, Dec. 3, 1930, V. 21, No. 5, p. 46-48.—Simple outdoor equipment has been installed by Shera Sand & Gravel Co., at its 300-ton plant near Richmond, Ind. A survey indicated possibility of selling locally as many concrete blocks as usual plant crew could produce during the usual idle periods. This has proved correct and program will be continued as it assures year-round employment. Operations include excavation, screening and washing of sand and gravel. Block machine produces 35 blocks per hr., each 8 in. by 8 in. Concrete is prepared in a worm-type continuous mixer. During past summer stock of pea gravel was maintained at minimum by this practice.—A. J. HOSKIN

Material producers making pipe. DUDLEY W. MOORE. *Rock Products*, Dec. 6, 1930, V. 33, No. 25, p. 89.—New plant of the Oklahoma Cement Pipe Co., Tulsa, Okla., is owned by Price Sand Co. and Hughes Stone Co., is also connected with Builders Concrete Co., which sells ready mixed concrete. The new pipe plant acts as an auxilliary plant for ready mixed concrete when this is desirable. Pipe plant produces 60 to 70 tons per day, largely storm sewer pipe handled by 2½-ton electric crane. An 800-ton octagon steel storage tank holds pipe materials. It has five compartments for stone and sand and cement compartment of underslung type, all fed by single elevator supplied from track hopper by an apron feeder. Bins are discharged by gravity to a 7-yd. weighing batcher. Batched material goes by conveyor system to a 21-cu. ft. mixer and heavy duty pipe making machine. Water is added from a measuring tank. Pipe is molded on a revolving table and then core is pulled by small electric hoist and molded pipe is sent to the curing room. Sizes are from 12 in. to 60 in. dia., sizes above 18 in. being reinforced. Curing is by placing pipe under water sprays for five days after which it is stored in the yard. All machines have individual motors with inclosed gear reducing units.—EDMUND SHAW

New concrete brick factory in Surrey. *Conc. Building Conc. Products* (England), Nov., 1930, V. 5, No. 11, p. 144.—An up-to-date factory for the manufacture of concrete bricks, is described, where bricks of all standard shades are made. Only mineral oxides are used as coloring agents, so there is no risk of fading. For partition walls, bricks are mixed 10:1 while 8:1 mix is used for external wall bricks. For greater strength 4:1 or 3:1 bricks are made. These bricks can be easily cut in any plane, and although they prevent penetration of moisture, they do not cause condensation. The materials are raised by a pump through a pipe line to three large settling bins beside the supplying lake, and to assist the raising, charges are exploded below water twice weekly. From the bins the sand is taken by jubilee skips to factory. Sand is cream colored, while cement and coloring material are ground together in ball mills specially designed. The proportions for the various colors are as follows: Red, 8 per cent of brick red oxide of iron by weight of cement; dark red, 8 per cent crimson red oxide; dark brown, 4 per cent crimson oxide plus 2 per cent mineral black; light brown, 4 per cent brick red plus 1 per cent mineral black; yellow, 5 per cent yellow ochre; tan or biscuit, 1¼ per cent brick red oxide; light stone, 2 per cent yellow ochre. The mixers used are of the pan type with two rollers which just clear the bottom of the pan, of 4 or 5 ft. capacity and turn out each about 1200 bricks per hour. The mixture is only sufficiently wet to bind if squeezed in the hands. From the mixer the materials are elevated to hopper over a revolving cylinder carrying three brick molds into each of which correct amount of concrete is rammed. Pallets are passed from discharge end of machine to steel racks and thence to curing shed. Bricks are kept moist for 48 hrs. At first they are sprayed with moisture to avoid pitting, then racks are covered and well saturated for rest of the 48 hours. For transporting to covered storage, portable roller conveyors with adjustable stands are used.—JOHN E. ADAMS

Materials

Aggregates

Two new gravel producing plants in Milwaukee district. Gordon F. Daggett. *Rock Products*, Dec. 20, 1930, V. 33, No. 26, p. 52.—Success with two sand and gravel plants in district well supplied with plants before they were built is ascribed to making specially prepared aggregates. At plant of Kohler Bros., Prospect Hill, Wis., sand was not washed originally as it was thought to be clean enough. Later both sand and gravel had to be washed to meet specifications, the sand by means of a double screw washer and classifier. At Central Sand and Gravel plant, Milwaukee, Wis., special washed sand was made by first passing sand through steel cylinder with lifting plates and baffle rings. After scrubbing in this cylinder everything is passed to a twin screw classifier and dewaterer. The washed product is stockpiled by belt conveyor.—Edmund Shaw

Preliminary tests on effect of size of aggregates on strength of concrete. C. E. Proudley. *Nat. Sand Gravel Bul.*, Dec., 1930, V. 11, No. 12, p. 13-18.—The laboratory of the National Sand and Gravel Association has carried out some preliminary tests in an effort to obtain some definite information on effect of size of aggregates on strength of concrete. One grading of sand and four gradings of gravel were used. The tests were made under the following conditions: The gravels, having different maximum sizes, were graded from fine to coarse in a similar manner; the sands and cement were of constant physical characteristics; and the consistency of the concrete as measured by flow table was same for all aggregates and proportions. While their principal value has been to point out some of requirements for more comprehensive investigation to be conducted in the future, following conclusions may be drawn from a study of results of these preliminary tests: (1) The coarser sizes of gravel gave higher strengths in compression and modulus of rupture than smaller sizes. For the average of proportions studied, the ¾ in. maximum size of gravel was about 12 per cent higher in compression and 7 per cent higher in transverse strength than the ⅜ in. maximum size. The 2 in. maximum size was about 11 per cent higher in compression and 8 per cent in transverse strength than the ¾ in. maximum size. (2) The richer mix, which also contained a higher proportion of sand, was less affected by changes in maximum size of aggregate than the leaner ones. (3) Test results showed fairly uniform relations between strength and water-cement ratio and between strength and void-cement ratio. They indicate that effects of changes in size of coarse aggregate were due to their influence on the quantity of mixing water required to produce uniform workability. (4) Coarse aggregates of different maximum sizes require different quantities of mortar to produce comparable workabilities. Accurate control of this factor is necessary in order to obtain proper comparisons. Further tests with particular attention to this factor are required to permit of more definite conclusions concerning effect of maximum size of coarse aggregate.—P. McKim

Dual washing system at new Clarence plant. *Rock Products*, Dec. 6, 1930, V. 33, No. 25, p. 33.—The new plant of the Clarence Sand Co., near Alexandria, New York, has a dual washing and screening system. The excavation is by 3-yd. scraper pulled by a 150 h. p. motor. This discharges to a hopper with a 30-in. belt conveyor feeder. A 24-in. belt conveyor takes the material to a 48-in. by 8-ft. vibrating screen with 2¼-in. mesh screen above and ¼-in. below. The oversize goes to 26-in. jaw crusher; intermediate sizes to double screw washer; the sand to the sump of an 8-in. pump. This pumps at about 80 per cent solids and 20 per cent water through a 6-in. pipe and it takes the place of an installation in which the sand was dewatered by drags and by screws and then carried by a belt conveyor. The washed gravel (with

crusher product added) goes to secondary washing plant above the bins. The gravel is rinsed and sized by vibrating screens and the sand is classified by a classifier with automatic discharge. The fine sands in the classifier overflow are recovered in automatic settling tanks.—EDMUND SHAW

Young men build one crusher stone plant. RAY F. SCHNEIDER. *Rock Products*, Dec. 6, 1930, V. 33, No. 25, p. 48.—At plant of Bussen Quarries, Jefferson Barracks, Miss., mining has superseded quarrying, the overburden being from 10 to 30 ft. Another quarry has been opened to be worked by an open pit. This will be used to supply stone in good weather and mining will be practiced in cold and bad weather. The stone is carried from the quarry face to the plant in 1¾-ton and 5-ton trucks. Entire crushing equipment is one "Jumbo" hammermill, which can reduce large rocks to 2 in. and finer in one operation. Feed opening is 36 x 42 in., fed by apron feeder. Crushed material goes by elevator to revolving screen, making four products. Oversize goes back to the crusher by a conveyor belt and chute. The minus ¾ in. goes to vibrating screen and other products directly to bin. Mixing conveyors below bins permit furnishing any desired combination of sizes.—EDMUND SHAW

Control and improvement of gauging of sand, gravel and river pebbles for concrete. A. JANOUSEK. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—It is the exception for gravel taken from river to correspond with rational requirements for concrete. One of most important objects of control is a granimetric analysis, as accurate as possible, promoting practical and economical improvement of aggregate, and determining what conditions govern strength and other required qualities of concrete. Chief points are: (1) Determination of sizes of stones and grains, their geometric shape, and importance to be attached to them as regards strength of concrete. (2) Determination of individual and total surfaces of grains, and influence of this on strength of concrete. (3) Determination of quantity of grains having equal dimensions, and relative proportions. (4) Application of these results to improve economically gravel as obtained. Usual procedure consists of successive siftings of natural mixture. Another way is to measure dimensions of grains directly, which, however, can be done only to a small quantity. Superficial area of grains can be found only approximately by experimental methods, or by calculation based on results of sifting. To make practical and economical use of these results a continuous control of works is necessary, and parallel with this control, a system of regulating mixture which must operate as automatically as possible and be independent of any initiative on the part of unqualified persons. There is still no satisfactory experimental method for determining exact surface area of stones. Effort has been made to give some indications on the subject of calculating this area, which is of great importance, especially in regard to tensile strength of concrete. Further, the author has examined important question of international unified methods of control, arriving at proposal brought forward in concluding paragraphs of paper; the gist of the matter being a series of screens answering both to scientific and to practical requirements, and suggestion being screens with circular holes .039, .118, .285, .590, 1.180 in., or .039, .079, .197, .394, .787 in. in diameter. Finally, very limited possibilities of using fineness modulus is dealt with and simple method of comparison of granimetric curves and of correcting random gravel is suggested.—EDITIONS LA TECHNIQUE DES TRAVAUX

Slag aggregate follows same course as others. *Rock Products*, Jan. 3, 1931, V. 34, No. 1, p. 144.—Production and sale of crushed slag shrunk 8 to 10 per cent in 1930. Prices were about same as in 1929. Even with present plants operating on 50 per cent capacity basis as indicated, several new plants were built during past year and many older plants were remodeled to operate

more economically. Employes of slag industry worked 75 per cent of time compared to 1929, with an indicated reduction of 25 per cent since 1928. Prices for 1931 are expected to remain at their present level with tonnages showing an increase, especially during the latter half of year. No changes are expected in employes' wages nor will there be an appreciable change in the number of men employed. Important new plants include Buffalo Slag Co., The Duquesne Slag Co., and Cashion Slag Co., the latter notable for simplicity of flow of material through plant. Birmingham Slag Co. is rebuilding its plant at Ensley, Ala., to have capacity of 2,000 lbs. National Slag Association opened a new research laboratory. In the JOURNAL of the Concrete Institute Proceedings, C. A. Hughes and A. S. Levens give some interesting information relative to the use of pulverized slag as a puzzuolanic material. In their tests, two kinds of volcanic ash, a blast furnace slag and burnt shale were used as puzzuolanic material and comparisons of compressive strength, shrinkage, etc., noted. (cf. A. C. I. JOURNAL, Dec., 1930; *Proceedings*, V. 27, p. 317). On compression tests in general, slag showed the greatest puzzuolanic activity and greatest strength. Shrinkage increased with increase in effective water to cement plus puzzuolana, slag being an exception to this rule.—EDMUND SHAW

Composition of mixing and application of concrete in engineering works. C. J. JACKAMAN. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—This paper, from point of view of a civil engineering contractor, endeavors to record outstanding features which might differentiate concrete works undertaken in England from those in other countries where different conditions prevail. Composition: Aggregates.—More readily available materials for these may be classified as: (a) for southern and southeastern parts of England (with some isolated areas elsewhere), natural river gravels and large areas of suitable sea beach gravels; (b) for districts in the southwestern, western, north midland, and northern parts, various igneous rocks. The former are in great demand and are more readily prepared for use as aggregate and hence in general prove economical; latter class of rocks requiring much more expensive production and preparation have not been so fully exploited. Preparation of aggregates has formed separate and increasingly important branch of concrete industry adjacent to large towns. For works of magnitude, however, every phase of preparation of raw material is commonly undertaken by the contractor on the works site, there being available power-driven machines for various operations of breaking natural rock to acceptable sizes, cleaning, screening and grading. Matrices. —Portland cement is preeminent among all other materials for matrix of concrete work. Improvement of its quality has been so continuous as to have almost entirely out-distanced use of other materials for the purpose. Rapid hardening varieties of portland cement have attained great popularity, justified by advantages they offer in many kinds of work. 1. Proportion of concrete. —For constructional works in England it is still invariable practice of engineer to assume responsibility for specifying proportions of constituent materials and usually maximum and minimum sizes for aggregates and sand. Determination of exact ratios of intermediate grading between limits assigned has not yet been generally adopted. Proportion is still almost invariably stated by measure of volume for coarse and fine aggregate; but for portland cement greater exactitude is sought by proportioning by weight. Little progress has been made in adoption of any method for relating proportion of mixing water to quantity of cement. Due check on quantity of water used is, however, maintained by increasing adoption of slump test of concrete after mixing. 2. Mixing concrete.—Various types of mechanical concrete mixers in general use are noted. "Batch" or non-continuous mixer, is most generally favored for securing uniformity of quality in product. Internal-combustion engines with petrol fuel have outstripped all competitors for motive power for these machines. 3. Distribution of concrete.—English engineers have shown great reserve in permitting use of automatic distributing plant and this attitude is receiving

support from importance now assigned to concrete having minimum water content consistent with easy manipulation. 4. Deposition of concrete.—No generally applicable, economical, and equally satisfactory method of consolidating concrete, when placed, has yet been produced to compare with carefully supervised manual effort. 5. Formwork.—Use of timber for formwork has not yet been challenged by any serious rival, owing to high initial cost of steel forms which forbids their adoption on any but large expansions of repetition work.—EDITIONS LA TECHNIQUE DES TRAVAUX

CEMENT

Studies on mixed portland cements—Part 6. SHOICHIRO NAGAI. *Kogyo Kwagaku Zasshi, J. Soc. Chem. Ind.* (Japan), 1930, V. 33, p. 279-85. Reviewed in *Zement* (Germany), Dec. 11, 1930, V. 19, No. 50, p. 1191.—Neo-Soliditit cement was made from slate mixtures. Soluble portion of slate was determined by successive treatments with sodium hydroxide solution (10 per cent) and hydrochloric acid (5 per cent). Mixtures of 55 to 85 per cent clinker and 15 to 45 per cent slate gave surprisingly high strength data, higher than pure cements.—A. E. BEITLICH

Studies on mixed portland cements—Part 7. SHOICHIRO NAGAI. *Kogyo Kwagaku Zasshi, J. Soc. Chem. Ind.* (Japan), 1930, V. 33, Supplemental binding, No. 6, p. 192-6B. Reviewed in *Zement* (Germany), Dec. 11, 1930, V. 19, No. 50, p. 1192.—Expansion and contraction of several kinds of cements: portland, blast furnace slag, high alumina and soliditit cements (to which certain colloidal materials were mixed in order to correspond with Japanese Neo-Soliditit) were studied. Specimens were heated from 392° to 1472° F. Great shrinkage led to complete destruction of several cement samples. High alumina cement showed greatest resistance. Portland cement shows a considerable increase of free lime content under this treatment. Same increase can be observed between 752° and 1112° F. in the case of soliditit cement and blast furnace slag cement, while free lime content drops sharply when heated from 1472° to 1832° F. A combination of free lime with acid constituents of colloidal materials seems to take place at such high temperatures. (cf. *Kogyo Kwagaku Zasshi, J. Soc. Chem. Ind.* (Japan), 1930, V. 33, p. 279-85.)—A. E. BEITLICH

Special cements and concretes. A. HASCH. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Maximum properties of cement and concrete can be considered from the general physical, mechanical and chemical points of view. The comparison of high early strength portland cement with Ciment Fondu (aluminous cement) shows that the latter is principally used on account of its greater capacity of resistance, as the high early strength of portland and cool setting cements is sufficient for majority of constructional requirements. Also they can be used for concreting at low temperatures. Statistical consideration of experimental results using Bernouilli law of the greatest number appears also to be an important method in future work of material testing.—EDITIONS LA TECHNIQUE DES TRAVAUX

Further developments in closed circuit dry grinding. H. G. WRIGHT. *Rock Products*, Dec. 20, 1930, V. 33, No. 26, p. 46.—Micro-photographs show that products made by reverse current air separation are more angular and therefore have more surface exposed than unclassified products. Hence they should burn more easily. Air classified material is shown to carry less oversize. That which makes good burning in kilns is not amount reduced below 200-mesh but that which is below 100-mesh. Tables are given comparing discharge of tube mills by gravity and air classified reverse current system. These show a less amount retained on 100-mesh for air classified products for pro-

portionately same grinding through 200-mesh. (cf. *Rock Products*, July 19, 1930, V. 33, No. 15.)—EDMUND SHAW

Examination of refractory materials for cement kilns. J. SCHAEFER. *Zement* (Germany), Nov. 20, 1930, V. 19, No. 47, p. 1112-3.—Durability of brick lining of rotary kilns depends largely on structure of bricks (shape and amount of voids and gradation), viscosity and chemical composition of clinker, reaction temperature, composition of bricks and duration of reaction. An improved method is described for testing of bricks under conditions which are similar to those encountered in actual mill practice. Bricks are heated in a high temperature furnace to different test temperatures and a powerful gas flame carrying raw mixture is blown against them. Effect of heat and reaction of clinker particles on brick surface can be easily determined. Also effect of great temperature changes on brick can be studied by rapid removal of brick from furnace. Chemical analysis of top layer shows depth of penetration and changes in composition. Photographs show different behavior of ordinary refractory brick, Dynamidon brick and Magnesidon brick.—A. E. BEITLICH

The grinding of cement and porosity of concrete. A. POULSON. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—No concrete is solid, and to secure greatest protection against chemical action (including that due to infiltration of pure water) a puzzolanic cement must be used to neutralize deleterious lime which will then unite with hydraulic constituents of puzzolana to form compounds like those in cement itself. In addition the "hydraulic index" should be tested and ought not to be less than ⅞; also mechanical strength. Reference is made to previous publications in respect of rational use of puzzolanas, and of their examination: 1912: New York Congress on Materials: *Cement in Seawater*. 1923: London Congress on Navigation; No. 53: *Portland cement in seawater and chemical value of puzzolanas*. 1924: Cairo Congress on Navigation: *Hydraulic mortar in seawater*. 1929: For Zurich Congress on Materials, 1931: *Compactness and chemical resistance of concrete*.—EDITIONS LA TECHNIQUE DES TRAVAUX

Fused cement and its influence in industry. EMIL STOCK. *Osterr. Bauzeitung* (Austria), Nov. 15, 1930, V. 6, No. 46, p. 752.—Resume in German of Italian article dealing with development of high alumina cement industry. Fused cements are used with advantage (1) for jobs which must be finished in a short time, (2) for winter construction and (3) for structures which are exposed to chemical actions or aggressive solutions. Rapid development of this type of cement led to increased efforts to improve ordinary portland cement and to study its physical and chemical properties on a scientific basis. (cf. *L'Industria Italiana del Cemento* (Italy), 1930, No. 5.)—A. E. BEITLICH

Researches on the rotary kiln in cement manufacture—Part 9. GEOFFREY MARTIN. *Rock Products*, Dec. 6, 1930, V. 33, No. 25, p. 54.—Heat required to decompose $CaCO_3$ at different temperatures is determined. This is usually taken to be 774 B. t. u. per lb. at ordinary temperatures. But calcite, raw material of cement, takes 756 B. t. u. per lb. From researches of several investigators, especially John Johnstone, a formula is worked out and steps are given in detail. From formula a table has been made giving the heat of disassociation of $CaCo_3$ in the rotary kiln. This shows that, beginning at ordinary temperatures, required heat is about 756 B. t. u. for calcite, but at 1443° F., (the lower limit of decomposition in rotary kilns) it is 685 B. t. u. At 1481° F. (upper limit of initial decomposition), it is 681.6 B. t. u. With increasing temperatures B. t. u. required decrease, dropping from 644.2 at 1832° F. to 341.1 at 3632° F. At 4940° F. no heat is required but there is evolution of 1.25 B. t. u. At 5432° F. there would be an evolution of 156.1 B. t. u. It would be impossible to secure this because of enormous pressure that would be required to keep $CaCO_3$ from splitting into CaO and CO_2 before reaching critical temperature of 4940° F.—EDMUND SHAW

Researches on the rotary kiln in cement manufacture—Part 10. GEOFFREY MARTIN. *Rock Products*, Dec. 20, 1930, V. 33, No. 26, p. 49.—In calculating amount of heat absorbed in making one pound of portland cement clinker, author assumes clinker containing 64 per cent CaO, 7 per cent Al_2O_3, 3 per cent Fe_2O_3, 22 per cent SiO_2 and 4 per cent non-essentials. To make 100 lb. there will be required 119.5 lb. $CaCO_3$, 18.46 lb. kaolin, 15.40 lb. hydrated silica, and 3.12 lb. ferric oxide. A study is made of each of these showing quantities of heat required to dehydrate, when this is necessary, and to raise material to temperature required to make clinker. The final quantity of heat required for 100 lb. clinker figures to 81,192 B. t. u. for decomposing $CaCO_3$, less 17,993 B. t. u. evolved in exothermic reactions, plus 28,665 B. t. u. absorbed in raising 100 lb. of clinker from 1481° F. to 2498° F., a net total being 91,864 B. t. u. Conclusion is that it should be carefully noted that it is fallacy to state total minimum quantity of heat required to make 1 lb. of clinker is 918.6 ÷ 652.5 = 1571.1 B. t. u., because this statement takes no account of quantity of heat recoverable from hot clinker and evolved gases. In making 1 lb. clinker raw material mixture must be subjected to steadily increasing temperature starting at 60° F. and finishing at about 2,498° F., and raw mixture must absorb 652.5 B. t. u. below 1,481° F. and 918.6 B. t. u. above 1,481° F. before 1 lb. clinker can be formed.—EDMUND SHAW

Studies on calcium ferrites and iron cements—Part 3 and 4. SHOICHIRO NAGAI AND KATSUHIKO ASAOKA. *Kogyo Kwagaku Zasshi, J. Soc. Chem. Ind.* (Japan), 1930, V. 33, Supplemental Binding No. 6 and 7, p. 190-2B, 256-9B. Reviewed in *Zement* (Germany), Dec. 11, 1930, V. 19, No. 50, p. 1191.—New data are presented of this comprehensive investigation (cf. *Kogyo Kwagaku Zasshi* (Japan), May, 1930, V. 33, Supplemental Binding No. 5, p. 161-4; JOURN. Amer. Concr. Inst., Dec., 1930, V. 2, No. 4, *Abstracts*, p. 96). Dicalcium ferrite, $2CaO.Fe_2O_3$, reacts with water in formation of calcium hydroxide which produces its strength properties. These decrease in water storage and stay fairly constant in air storage. Constancy of volume of dicalcium ferrite mortar was studied by Bauschinger and Le Chatelier methods and compared with properties of portland cement and Kuhl cement. When mixtures of SiO_2, Fe_2O_3 and CaO are fused between 2552° and 2732° F., calcium ferrite is formed first, then combination of CaO and SiO_2 to di- and tricalcium silicate takes place. Synthetic mixtures in the field SiO_2—Al_2O_3—Fe_2O_5—CaO were prepared by replacing 1 part of ferric oxide (8-9 per cent) by alumina (2-3 per cent) at temperatures between 2552° and 2732° F. Cements consisted of about 15 to 16 per cent dicalcium ferrite, 6 to 7 per cent tricalcium aluminate and various amounts of di- and tricalcium silicate. Formation of tricalcium silicate was only possible, when ferrite or aluminate were present.—A. E. BEITLICH

Studies on calcium ferrites and iron cements—Part 5. SHOICHIRO NAGAI AND KATSUHIKO ASAOKA. *Kogyo Kwagaku Zasshi, J. Soc. Chem. Ind.* (Japan), 1930, V. 33, Supplemental Binding, No. 8, p. 312-5B. Reviewed in *Zement* (Germany), Dec. 11, 1930, V. 19, No. 50, p. 1192.—Temperature of combination of iron cements lies above sintering temperature of ordinary portland cement due to small amount of calcium aluminates. These temperatures are between 2642° and 2732° F. Chemical composition is about 65.2 per cent CaO, 23.3 per cent SiO_2, 2.50 per cent Al_2O_3 and 9.00 per cent Fe_2O_3 and their constitution is approximately 52.2-54.5 per cent tricalcium silicate, 20.2-23.7 per cent dicalcium silicate, 3.5-5.8 per cent tricalcium aluminate and 14.8-16.0 per cent dicalcium ferrite. Molecular ratio between CaO and SiO_2 is between 2.62 and 2.67. Strength data obtained by small-piece testing methods are lower than ordinary portland cement strength.—A. E. BEITLICH

Properties of Concrete

The ideal gauging of concrete mixes. H. Imberechts. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—The object of the researches dealt with in this paper is to establish a method of calculating proportions for concrete mixes based upon knowledge of curves of granimetric composition for elements involved. Investigation starts with the Fuller-Bolomey curve, $P = A + (100 - A)\sqrt{d/D}$. After determining best value for constant A, percentage of fine elements, including cement, not exceeding 0.02 in. size, which corresponds to the strongest concrete—for a given water content—still easily workable and of satisfactory appearance when fractured, researches were extended to cover all acceptable mixtures between two limits. The lower limit was introduced to secure concrete still easily workable into place, the upper limit to restrict falling off in strength. Reason for laying down these limits is impossibility of making particular cases conform precisely to a given "typical composition"; it is necessary to allow certain tolerances, and curves of "limiting composition" furnish tolerances which can be prescribed.—Editions La Technique des Travaux

Control of concrete construction of the German railroad concern (Reichsbahn). Vogeler. *Report 33rd main meeting German Concrete Association*, March 17, 1930, p. 236-61.—After discussing contents of recently issued German specifications for mortars and concrete, author describes field control outfit and equipment for stationary concrete control laboratories. All materials: cement, lime, trass, aggregates and mixing water are submitted to careful examination. Concrete is tested for its tensile, compressive and flexural strength, water permeability and resistance against aggressive solutions. Furthermore, admixtures, water proofing materials, protective coatings and bricks are examined. Detailed description is given of equipment and machinery for strength and other tests. Special consideration is given to sieve analysis and exact proportioning of aggregate gradings. Samples of good concrete and concrete that failed, with necessary explanations facilitate understanding of specifications. Progress during first year is very satisfying. Program for second year includes examination of methods and materials for water tightening of concrete foundations, protective coatings, plasters and surface finishing. These will be studied especially on abutments, supporting walls, piers, bridges, culverts and tunnels.—A. E. Beitlich

Deterioration of concrete in hydraulic structures. A. Ekwall. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Inspections of hydraulic structures in Sweden displayed some defects in concrete 10 years old. Continued observations proved, that concrete in some cases was subject to increasing deterioration, apparently due to qualities of concrete materials, to methods of making concrete or to conditions of exposure. Investigations above described were arranged to ascertain causes of such increasing deterioration. It had been observed that deterioration occurred only in structures exposed to water on one side and was caused by solubility of lime and decomposition of other chemical combinations in hydrated cement. Particular attention was therefore placed on solubility of cement and aggressiveness of water. In combination with investigation relating to these factors, practical experiments have been made with concrete exposed to low water pressure for several years. Investigation proved that Swedish natural waters need not be considered aggressive in this respect. Importance of using sand, relatively free from organic substances, was impressively established. Leaner mixtures than 1:4½ should not be used for concrete exposed to water pressure from one side. Replacing cement by an admixture of 10 per cent lime or 5 per cent calcium chloride improved watertightness,

while 25 per cent trass or slate powder gave practically no improvement. - EDITIONS LA TECHNIQUE DES TEAVAUX

Investigation of the behaviour of cement mortar in hot water. "Versuche ueber das verhalten von zementmoertel in heissem wasser." OTTO GRAF. Report of the Institute for Testing Materials at the Technische Hochschule in Stuttgart (Germany), during the years 1928-1929; Publication No. 62 of German Committee for reinforced concrete. Berlin 1930, Wilhelm Ernst und Sohn, R. M. 4.30. Reviewed in *Bautechnik* (Germany), Dec. 5, 1930, V. 8, No. 52, p. 770.—Test pieces of portland cement, high early strength cement and high alumina cement were exposed to water of 68, 122 and 194° F. Permanent storage of testpieces in hot water (194° F.) resulted in an increase in strength of lean mixtures (1:6) while rich mixtures (1:3) lost some of their strength. Behavior in water of 122° F. was varying according to different kinds of cement. Frequent rapid changes of temperature led to considerable reductions in strength and were different with different cements. Conclusions are drawn concerning use of such cements for special structures (hot water tanks).—A. E. BEITLICH

The effect of temperature on flat arches constructed of reinforced concrete. CHARLES S. GRAY. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—First part studies temperature range which may be expected in an arch, variation of temperature throughout the bridge and ratio of internal to external temperature. Second part treats three hinged arches and considers movement of crown hinge and change in horizontal thrust for a temperature variation of 30° F. Third division considers arches of two hinges; curves and tables are given showing variation of temperature thrust and temperature moment at all points of span for various ratios of rise to span for any temperature range. In fourth section are treated arches without hinges; curves are given to show variation of temperature thrust and temperature moment at all points in span for various ratios of rise to span. Fifth section considers effect of change of shape of arch axis upon temperature thrusts and moments.—EDITIONS LA TECHNIQUE DES TRAVAUX

Experiments with columns reinforced with steels of high strength properties. R. SALIGER. *Osterr. Bauzeitung* (Austria), Nov. 1, 1930, V. 6, No. 44, p. 723-30.—Progress of joint investigation of a German and an Austrian institute for testing materials on the subject of reinforcing of concrete columns is reported. Tests with steels of high quality are finished and results reported. Eight different types of columns with octagonal cross-section and circumferential reinforcements of 0.78-in. hoop irons or 0.2-in. round steel were broken. Longitudinal reinforcements consist of 4, 6 or 8 steel rods, 1.18 in. and 1.65 in. thick. Diameter of columns is 13.8 in., their length is 4 and 9.8 ft. Tests in Vienna were made with columns, reinforcements of which were welded in center. Tables show changes in form of columns when exposed to pressures from 10 to 200 tons. Under high pressures, uniformity between column core and outer layer is destroyed. Columns of 9.8 ft. length show a 15 per cent lower compressive strength than 4-ft. columns. Columns with welded reinforcements are of no advantage. Results of tests are carefully analyzed and conclusions are drawn for application in practice.—A. E. BEITLICH

Changes in the action and strength of hyperstatic reinforced concrete structures with time. H. LOSSIER. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Concrete undergoes with time a number of changes modifying action of reinforced concrete structures both from point of view of elasticity and of strength. The former changes, in structures which are hyperstatic, affect sharing loads between the different members. Although generally speaking it does not appear

a priori that these changes are of such nature as to affect safety of the works, yet it is important that question should be studied and checked by experiments in hope of arriving at a solution.—EDITIONS LA TECHNIQUE DES TRAVAUX

Measurement of temperature in concrete during its hardening. F. G. PEREZ. *Ingenieria* (Mexico), Nov., 1930, V. 4, No. 11, p. 418-420.—Small cracks in the buttresses of the Rodriquez Dam (Ambursen Type) in lower California were investigated by a group of consulting engineers who concluded that temperature developed in interior of mass during hardening was one of the causes. This led to investigation of effect of fineness of cement on temperature produced, the data from which is shown graphically in the report. The investigation compared a cement ground to 94 to 96 per cent passing a 200-mesh sieve with one that had 84 to 86 per cent passing that sieve. Temperature measurements were made electrically with resistance type pyrometers inserted in the concrete at five points. Readings were taken at short intervals during first day and at increasing intervals thereafter until they became practically constant. Temperature during setting of concrete made of finely ground cement reached 78° F. while air was 67° F. Concrete made of more coarsely ground cement reached 71° F. while air was 53° F. Temperature of concrete ascended for three days for finely ground and four days for coarsely ground cement. Maximum temperature attained in the concrete with finely ground cement was 126° F. and 118° F. with the coarsely ground cement. Both kinds of cement maintained a temperature higher than surrounding air for two weeks. Maximum temperatures were obtained within four ft. of the exposed side of concrete.—C. G. CLAIR AND M. N. CLAIR

Report on the Swedish investigations and experiences concerning shrinkage and temperature in concrete. N. ROYEN. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Great variation in temperature (95° F. to —56° F.) existing in some parts of Sweden have made it necessary to pay particular attention to such factors as heat generated by setting and hardening of concrete and the influence of temperature and shrinkage. Investigations have been made to find relation between temperature of concrete and air temperature for different slab thicknesses. Heat generated during setting has been investigated by experiments for a number of different brands of cement. Amount of high alumina cement required to obtain, by heat generation, a sufficiently high temperature for curing concrete made at temperatures below 32° F. and effect of low temperature on hardened concrete have been objects of other investigations. Results of experiments on shrinkage and swelling of concrete are given, and finally are stated some measures taken in design and construction of dams in northern Sweden to decrease effect of temperature and shrinkage.—EDITIONS LA TECHNIQUE DES TRAVAUX

The consistency of cast stone. H. A. HOLT. *Conc. Building Conc. Products* (England), Jan. 1931, V. 6, No. 1, p. 2.—The difficulty of measuring consistency is pointed out, since slump tests are for use with much wetter mixes than are encountered in the manufacture of cast stone. "Dry" refers to a mortar which will ball in the hand and leave it clean, but will break and crumble when dropped. It may be mechanically tamped in a mold without the appearance of moisture on the surface, and without becoming plastic. "Semi-dry" mortars will ball in the hand and leave it clean, but when thoroughly tamped in a mold, will become just plastic but no more, and water can just be seen on surface. "Plastic" mortar will just moisten the hand and will ball, barely fails to slump, and will not flow down an inclined plane, but when tamped becomes a stiff quaky mass with some moisture on the surface. For strongest, densest and most impermeable concrete minimum amount of water required to produce plasticity only, must be used. In case of 1:2:4 concrete, 6 per cent water by weight of total dry mixed materials would thus be required.

In many methods of manufacture of cast stone, wet mixes are unavoidable. In case of spun concrete moisture is brought to surface by centrifugal action and is removed before concrete has hardened. On account of excessive labor cost, dry mixes are only practicable with mechanical tamping or consolidation. When little mixing water is used proper curing is essential for case hardening the concrete, and completing hydration of cement on the surface. Experiments show that maximum temperature accompanied by saturated humidity produces maximum strength in minimum time. For surfaces which are to be tooled or brought to an ashlar finish, fine sand and semi-dry or dry mixes are recommended. Wet mixes give better results when coarser aggregates are used, and polished or scrubbed surfaces are required. Plastic concrete tends to produce less crazing and greater adhesion of cement to reinforcement, less risk of disintegration by frost or acid atmospheres than dry and semi-dry mixes, but is less speedy in production.—JOHN E. ADAMS

The grinding of cement and porosity of concrete. (See MATERIALS—CEMENT)

ENGINEERING DESIGN

BUILDINGS

New construction of a recovery home for children in Koenigsfeld (Germany). ALFRED FISCHER. *Zement* (Germany), Nov. 13, 1930, V. 19, No. 46, p. 1092-3.—Building is made as homogeneous reinforced concrete skeleton structure and satisfies all demands of modern hygiene. Cantilevered construction of second floor forms roof above dry, open air playground and is supported by reinforced concrete columns.—A. E. BEITLICH

Progress of experimental statics of rigid frames. F. KANN. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Method developed by author for experimental solution of frames with a high degree of rigidity rests on direct measurement of rotation of joints and bars of a system elastically deformed. In this purpose he has made use of a novel manner of constructing model of bars of celluloid joined at corners by blocks of hard wood which permits of production of very considerable deformations. By design of elastic member and measurement of angles of tangents and chords we can measure exactly rotations, which allows of calculation of moments at joints or their ratios useful for completing or controlling the calculations. Comparison has been made for frames without struts at angles and for frames with struts reaching to 1/5 of length of beams and uprights. Measured angles agreed closely with calculations when taking action of struts into account. Use and development of method in practice for systems with a high degree of rigidity is therefore very promising.—EDITIONS LA TECHNIQUE DES TRAVAUX

Collapses of reinforced concrete structures. LUIGI SANTARELLA. *Osterr. Bauzeitung* (Austria), Nov. 22, 1930, V. 6, No. 47, p. 764—Reasons for collapses of reinforced concrete structures are classified in 4 groups: (1) errors in calculation, design or construction, (2) impracticable construction or erroneous reading of blueprints, (3) bad condition of structural materials or incorrect mixtures and (4) too early removal of forms and lack of protection against unexpected damages. Directions to remedy such faults are given. (cf. *L'industria Italiana del Cemento* (Italy), June 1930.)—A. E. BEITLICH

Tests to destruction of a reinforced concrete floor. L. VANDEPERRE. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Tests described had two objects: (1) determination

of factors of safety—with regard to initial cracking of concrete—exceeding limits of elasticity of steel and final rupture of a complete structure constructed of reinforced concrete. Calculated on bases of hypotheses commonly accepted in resistance of materials and stability of constructions. This complete structure was a normal floor of slabs and lower ribs of 20 ft. and 25 ft. made in the yard, without particular care or special supervision, by workmen usually employed on similar work. 2. Determination of same dimension comparable with first for calculated permissible loads, and made under same conditions but of which organic conception is based on use of concrete in very thin curved slabs stiffened by their curvature. Tests consisted of loading to breaking point two floors and measuring deflection of principal beams. Preliminary calculations, description of test loads and measurement of deflections are reviewed with description of tests with photographs and diagrams of cracks and of rupture. Tables and diagrams review results of tests and other tables review comparative conclusion as to resistance and cost of two systems tested. In conclusion the following points are cited: (1) Regularity of mixing without particular care. Special supervision has been within about 15 per cent. (2) The factor of safety against initial cracking in normal floor has been less than 1.0 for one of the beams. A mean value would be about 1.2. But unfavorable circumstance as concreting in very dry and warm weather may have made it fall below 1.0. For the special slab it was equal to about 1.17. (3) The factor of safety to exceeding the limits of elasticity of the steel was 2.4 for the normal floor and 3.0 for the special floor. (4) Factor of safety against rupture was greater than 3.6 for normal floor which could not be loaded to destruction but which would have certainly failed by drawing of the steel. It was equal to 3.49 for special floor which failed prematurely by crushing of concrete in compressed portion of marginal beams, a central drum doubly reinforced would have rendered the section of rupture rigid transversely and thus increased security of the whole. (5) All failures by bending by crushing of concrete have occurred by stepping along planes oblique to compressive stress. (6) Refacings or renderings have behaved perfectly up to point of rupture, these inevitable repairs serve then in practice to perfect work from point of view both of resistance and appearance, and it is therefore necessary to be doubly careful in this respect and not to treat them as mere added veneer.—EDITIONS LA TECHNIQUE DES TRAVAUX

Reinforced concrete in Great Britain. A. KIRKWOOD-DODDS. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, 1930.—First reinforced concrete structure designed by Hennebique was erected in Belgium nearly 50 years ago and some noteworthy examples of his early work are to be found in the city of Liege today. Having been convinced by practical experience of possibilities of concrete in combination with steel, Hennebique formulated a complete method of design and in 1892 established his well-known headquarters in Paris, whence the Hennebique system was spread throughout Europe and to almost every part of the world. Great Britain was not far behind France and Belgium in taking up the new method of construction, for in 1896, the late L. G. Mouchel became the pioneer of this form of construction in that country. Much effort was necessary before reinforced concrete was accepted by British engineers and architects, but in 1898 its claims were recognized by the chief engineer to the Mersey Docks and Harbor Board and by the Great Western Railway engineers, and a little later, Mr. Mouchel was appointed consulting engineer for New General Post Office, London. At time of Mr. Mouchel's death in 1909, some 800 reinforced concrete structures had been completed in the United Kingdom. In referring briefly to methods of calculation, it is pointed out that several structures described were designed by means of formulae evolved by Hennebique some 40 years ago, and ever since then used with consistently satisfactory results, a record attributed to the fact that the formulae and the essential factors used in their practical application were derived from scientific tests and actual

experience. Some typical examples of reinforced concrete building construction on a large scale in Great Britain, referred to are: General Post Office Buildings, London.—Comprising two blocks connected by a two-story basement, these buildings have a total volume of 8,500,000 cubic feet. They were designed on the monolithic skeleton principle, all loads, including that of architectural masonry, being carried by reinforced concrete construction. Buildings embody interesting structural details and use of reinforced concrete resulted in a very large reduction of capital expenditure. Royal Liver Building.—This conspicuous landmark on quayside in Liverpool rises 360 ft. above foundation, and is 301 ft. by 177 ft. in plan. Masonry enclosing walls are carried entirely by a monolithic reinforced concrete skeleton. Long span beams, interior arches and main columns, carrying loads up to 1,500 tons each are some features of building. Government Stationery Office, London.—An impressive example of reinforced concrete work, including two eight-story buildings, one 106 ft. by 80 ft. and other 480 ft. by 215 ft., connected by a three-story bridge. Wall panels of skeletons are mainly occupied by windows, providing admission of natural light. Railway Station and Warehouse, Newcastle-on-Tyne.—Building, 430 ft. by 178 ft. in plan by 83 ft. high, comprising high and low level railway stations, with six lines of rails, above them being a three-story warehouse and a flour storage of 500,000 cu. ft. capacity with sloping floors supported by reinforced concrete lattice girders carrying loads up to 300 tons each. After over 25 years of heavy continuous duty, structure still justifies Hennebique methods employed in its design. Dock Warehouses and Grain Silos.—The first example is a range of five transit sheds at Manchester docks, with frontage of 2250 ft. and depth of 112 ft. from front to back, total floor and roof area being nearly 22 acres. Unusual feature is railway tunnel passing obliquely through one of buildings. Among other grain silo buildings in Manchester docks is one with a storage capacity of 1,680,000 bu., the largest structure of its class in Great Britain. Another interesting example is group of six cylindrical silos near Newcastle-on-Tyne, each compartment being 72 ft. high by 45 ft. in diameter, embodied in a structure 176 ft. by 92 ft., 109 ft. high.—EDITIONS LA TECHNIQUE DES TRAVAUX

BRIDGES

Pyke's Creek bridge. GEOFFREY OWEN THOMAS. *J. Inst. Eng.* (Australia), Oct., 1930, V. 2, No. 10, p. 369.—Paper deals with choice, design and construction, and testing of a 5-span continuous reinforced concrete road bridge, 246 ft. long, over a reservoir near Bacchus Marsh, Victoria. With such long spans, considerable economy is obtained by using beams of widely varying moment of inertia, the deep haunches greatly reducing the positive moment in mid-span. Temperature and secondary stresses are investigated. Erection was simplified by incorporating, as reinforcement, in the superstructure, a light welded steel truss, from which forms were supported. Deflection tests were found to agree with calculated values if E is taken as 6,000,000 lb. per sq. in. The average compressive strength of test cylinders was 3770 lb. per sq. in. Tests proved the waste in adhering to value of E equal to 2,000,000 in cases where concrete is properly supervised in construction. Detailed calculations are included.—JOHN E. ADAMS

Working stress of 1,200 lb. used for 39 ft. concrete slabs. CLARK H. ELDRIDGE. *Eng. News Record*, Dec. 18, 1930, V. 105, No. 25, p. 981-982.—Reinforced-concrete slab construction on 39-ft. spans with concrete working stresses of 1,200 lb. per sq. in. was required by the limited head clearance at the Second Avenue extension viaduct in Seattle. Construction includes use of several unusual details, including an unsupported expansion joint through a 15-in. slab, using steel dowels and a novel method of supporting slab on lower flange of a plate girder. Live load was taken as two 20-ton trucks with allowance of 100 per cent on rear axle of one truck. Working stress in steel was taken at

16,000 lb. per sq. in. Under these conditions slab thicknesses for four spans were 12, 13, 15 and 12 in. respectively. Main reinforcement consisted of 1⅛-in. round bars at 4-in. centers for the 36 and 39-ft. spans, with ½-in. round spacer bars at 4 ft. intervals. Concrete was designed for 3,000 lb. per sq. in. and a fiber stress of 0.4 of this value or 1,200 lb. was adopted. Strength of concrete in structure, as shown by 27 test cylinders broken at 28 days, averaged 3,559 lb. per sq. in. with a high strength of 4,760 lb. and a low strength of 2,380 lb. Two expansion joints were provided about 60 ft. apart at right angles to supporting bents. These joints necessitated some method of distributing heavy wheel loads between adjacent slabs. This was done by encasing the edges of the slabs in steel channel sections, anchored into edge of concrete by means of steel straps, and using heavy steel dowels to transmit the load across the joint. Backs of channels are spaced 2½ in. apart to allow for expansion.—D. E. LARSON

Design of arched bridges with fixed supports. H. CARPENTER. *Concrete Constr. Eng.* (England), Dec., 1930, V. 25, No. 11-12, p. 612-622, p. 673-685.—Method is given of obtaining moments and stresses due to live load, and is based upon assumption that uniformly distributed live load can be used in place of usual procedure of using influence line. Investigations were restricted to critical sections at crown and springing. From study of properties of influence line maximum positive moment at crown is obtained by loading central part of the arch. Values of moments, vertical reactions at supports and horizontal thrust are obtained using influence line by superimposing unit loads at most unfavorable positions. Maximum values of moments, vertical reactions and horizontal thrusts are thus obtained. However, moment = αwl^2, horizontal thrust = $\beta wl^2/r$ and vertical reaction = γwl, where w = the unit load per ft. and α, β and γ are coefficients. By equating the results obtained by use of the influence lines to these expressions corresponding values of coefficients, α, β and γ are obtained. Values of these coefficients are given for different rise-span ratios and for different ratios of depth at crown to depth at springing. Tables of coefficients are given for parabolic, open spandrel and filled spandrel arches. It is necessary to know values of uniform load w in order to use above coefficients to obtain moments, thrusts and reactions. Values of equivalent uniform load w were computed by use of influence line and actual wheel loads. Equating values thus found to values in terms of w, values of w were obtained. Results of these investigations are plotted giving values of equivalent uniform load w for spans varying from 25 to 400 ft. Curves are plotted for negative and positive moments at springing, positive moment at crown, horizontal thrust at crown and springing, and vertical reaction at springing. Study was made to determine the relation between spacing of longitudinal beams and resultant load imposed upon arch ring. A point of interest from a study of tables of coefficients for moments is that as the ratio of the springing thickness increases, arch axis remaining the same, moments at springing increase, but moment at the crown decreases. The result is a reduction of moment at center and a corresponding increase of moment at support. Application is made of the above method to an open spandrel arch of 150 ft. span, rise of 22 ft. 6 in., depth at crown of 2 ft. 3 in. and depth at springing of 3 ft. 4½ in. Stresses are computed and a comparison made between the approximate method presented and the "exact" method showing close agreement. Value of the horizontal thrust by the "exact" method is 78,000 lb. and by above approximate method is 82,200 lbs.—JOSEPH MARIN

DAMS

New type of arched dam. A. PENA BOEUF. *Summary Reports*, First International Congress for Concrete and Reinforced, Concrete Liege, 1930.—Serious difficulty in calculation of arched dams, in which certain hypotheses must be made to consider relative influence of jutting in the foundation and

the side walls, is radically corrected in type of dam proposed, and in which in addition to suppression of indeterminate factor of elasticity, there is an enormous saving in amount of materials used. Fundamental principle is the division into horizontal isostatic arches and the ease with which the calculation of elasticity can be applied to them.—EDITIONS LA TECHNIQUE DES TRAVAUX

Stresses in dams. S. CAROTHERS. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—The usual graphic method of obtaining stresses in dams necessitates beginning at the top and working downwards towards the base. It will thus be seen that any error in earlier part of work will be perpetuated to the end and will vitiate results obtained for lower part of dam. Paper gives a method of obtaining stresses at base by a direct process of calculation and this should prove useful as a check on stresses as found by graphical methods. In addition, the paper introduces polar coordinates which have great advantage that for dams of approximately triangular section the principal stresses are obtained direct for the front and flank of the dam. These are points where stresses have maximum values. Stresses are obtained from Airy's stress function x by methods fully explained in Love's Elasticity.—EDITIONS LA TECHNIQUE DES TRAVAUX

MISCELLANEOUS

Calculation of secondary effects in composite girders. A. PENA BOEUF. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Considering these girders, for purpose of calculation, as an articulate isostatic system, to each diagonal one applies the corresponding tensile stress and when these diagonals are virtually suppressed, the girder is calculated as a Vierendeel girder. To the law of moments resulting at each joint, the distribution is applied to the parts which meet thereon, in accordance with the relative flexibility of each.—EDITIONS LA TECHNIQUE DES TRAVAUX

Reports on new experiments concerning reinforcing of concrete beams against thrust stresses. OTTO GRAF. *Report 33rd main meeting German Concrete Association*, March 17, 1930, p. 137-42.—Results of three series of tests on reinforced concrete beams are reported; special consideration was given to reinforcing against thrust stresses. Several weak points in German specifications for reinforced concrete of 1925 are discussed and certain changes are proposed.—A. E. BEITLICH

Tests on columns of bound concrete reinforced with bars of special steel and welded. R. SALIGER. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—1. Tests deal with columns of bound concrete with a high percentage of reinforcement of special steel. 2. Load carried results in every case from the sum of the resistance to compression of concrete core and longitudinal reinforcement as well as from resistance to extension of binding. 3. The share of resistance of concrete amounts to $\frac{1}{3}$ to $\frac{1}{6}$ according to importance of reinforcement, which reinforcement supports from $\frac{2}{3}$ to $\frac{5}{6}$ of the total load. 4. Welded longitudinal reinforcement has a resistance to compression 10 per cent inferior to that of non-welded bars. 5. On account of their high resistance to compression the section of such columns should not occupy more space in the structure than columns of rivetted steel.—EDITIONS LA TECHNIQUE DES TRAVAUX

Design of circular tank of reinforced concrete. I. L. RASMUSSEN. *Eng. News Record*, Dec. 11, 1930, V. 105, No. 24, p. 923-925.—The designer of circular tanks of reinforced concrete has to overcome theoretical obstacles not generally met with in design of other structures. The walls of the tank are

rigidly fixed to the base, which, for purpose of analysis, may be considered immobile. The radii of the cylindrical sides tend to lengthen under pressure. At base, the walls are completely restrained and their radii cannot change in length. As distance from base to any horizontal section of wall increases, the unrestrained movement of walls also increases until a point is reached where movement is entirely unrestrained. To determine this distance and the moments and stresses which are set up between the base and this point through the restraint of the base is chief problem to be solved in design of circular tanks. The author presents a simple and direct mathematical analysis for determining these moments and stresses.—D. E. LARSON

Articulated concrete revetment construction on the Mississippi River. MORRIS W. GILLAND. *Eng. News Record*, Dec. 25, 1930, V. 105, No. 26, p. 996-1003.—Early in the task of regulating the Mississippi River for navigation and flood protection, it was manifest that some of its banks must be prevented from caving. Gradually brush mattress superseded all other types of revetment structure until 1915 when its position began to be contested by concrete. Concrete was the first thought because it had served well for upper bank paving, was even more durable under water and suffered little from being alternately wet and dry. The articulated-mat revetment being used at present consists of a series of lapped mats extending from waters edge to bottom of underwater bank and outshore on river bottom some 50 ft. farther. Each mat is 140 ft. wide alongshore and from 300 to 350 ft. long outshore from the water's edge. Adjacent mats overlap 10 ft. Each mat is made up of sections, 4 by 25 ft. strung on steel cables, which extend upbank and are anchored inshore. Construction consists of four operations: (1) fabrication of articulated mat sections; (2) grading upper bank to 1 on 4 slope; (3) assembling and sinking sections to make continuous revetment; and (4) paving sloped bank with concrete. Each of four operations requires separate plant (c. f. A. C. I. JOURNAL, June, 1930, p. 799, *Proceedings* V. 26, 1930).—D. E. LARSON

Nomogram for calculating average diagonal tension in a given section of beam. JORGE QUIJANO. *Ingenieria* (Mexico), Nov., 1930, V. 4, No. 11, p. 422 and 427. A simple nomographic chart, one of a series for use in reinforced concrete design, for investigating diagonal tension in beams. Left hand scale, diagonal tension T; center scale, difference in moment between sections A and B; and right hand scale, depth d for various angles of stirrup. All in metric units, with explanation of use on chart and opposite page.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating simple rectangular slabs and beams. JORGE QUIJANO. *Ingenieria* (Mexico), Oct., 1930, V. 4, No. 10, p. 390-391.—A simple alignment chart, one of a series for use in reinforced concrete design. Left hand scale, depth of slab d, middle scales, moment M and area of steel A^s, and right hand scale width b, all in metric units. Explanation of use is given on the chart and opposite page.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating slabs freely supported or partially restrained. JORGE QUIJANO. *Ingenieria* (Mexico), Oct., 1930, V. 4, No. 10, p. 378-379.—A simple nomographic chart, one of a series, for use in reinforced concrete design to determine thickness of slab and area of steel. Left hand scale, span; center scale, depth of slab and area of steel; and right hand scale, load; all in metric units. This chart is for f_s = 20,000 lb. per sq. in., f_c = 900 lb. per sq. in. and n = 15. Explanation of use is given on chart and opposite page.—C. G. CLAIR AND M. N. CLAIR

Reinforced concrete bunkers in Germany. *Concrete Constr. Eng.* (England), Dec., 1930, V. 25, No. 12, p. 669-673.—During recent years large number of coal and coke bunkers have been constructed in Germany, some notable for long spans and heavy loads on main girders, and provision made

for possible settlement of ground due to mining operations. Total height of reinforced concrete bunker at Alsdorf is 170 ft. The capacity is 3,000 tons of coal. It is 78 ft. high and 79 ft. by 49 ft. 3 in. in plan. Due to the large space required by the cable drums, it was necessary to cantilever upper part of the structure on two sides. Foundation slab is 62 ft. 3 in. by 49 ft. 3 in. by 4 ft. thick with ribs projecting to a height of 11 ft. 6 in., thus reducing the maximum pressure on the ground due to dead and live loads and wind, to 3¾ tons per sq. ft. Owing to possibility of subsidence due to mining operations, the foundation was designed to resist stresses arising from uneven settlement of ground, and it is possible for whole structure to be inclined at angle of 5 degrees with vertical before dangerous stresses occur. Bunker is supported on four main columns, 16 ft. 5 in. by 4 ft. 1 in. cross section. Provision has been made for restoring structure to its original position if any settlement or canting takes place. Structural details of bunker are given.—JOSEPH MARIN

Angular rotation method for the analysis of multiple span frames. R. A. FREEMAN AND A. S. GILMAN. *J. Boston Society C. E.*, Dec., 1930, p. 543-562.—There is given the development of the fundamental equations for analysis of statically indeterminate frames based on the work of Ernest Suter entitled, "Die Methode der Festpunkte," published in 1923. Two numerical examples are worked out to illustrate the method. The angular rotation method is particularly valuable for analysis of multiple-span rigid frames.—MILES N. CLAIR

Thin reinforced concrete slabs. J. H. H. WILKES. *Roads and Rd. Constr.* (England), Dec., 1930, V. 8, No. 96, p. 434.—In case where steel is cheap, it may be more economical to employ floor slabs in bridges, or similar structures, in which the steel is greater than normal. In this case strength of slab will be determined by that of concrete. Curves show relationship between moment of resistance and percentage of steel, for various stresses in the concrete or the steel. Shear will be limiting factor for thickness.—JOHN E. ADAMS

Field inspection of concrete pipe culverts. R. W. CRUM. Iowa State College *Eng. Expt. Station* Bull. No. 99, Sept. 3, 1930.—In 1915, a question having arisen as to suitability of concrete pipe for use as highway culverts, Iowa Highway Commission and Engineering Experiment Station of Iowa State College cooperated in making a field study of such structures. Forty-six culverts ranging in size from 24 to 66 in. diameter were inspected. Inspections showed older designs to be inadequate, and since 1915 stronger and heavier pipe have been used. Records are given of certain culverts covering a life of 22 years, as oldest pipe examined in 1915 was then about 9 years old. Method of inspection was to crawl through pipe, making a thorough examination of all significant features by means of a flashlight. Principal opinions are: Concrete pipe made of good concrete and used in locations in which load on pipe does not exceed its supporting strength, and so installed that water flowing through (hydraulic traffic) cannot undermine support for the pipe, will make satisfactory culverts that can be classed as permanent as other concrete construction. The culverts examined did not exhibit progressive deterioration to an extent great enough, or in such a way, that predictions as to the length of life could be made therefrom. Culverts were found to be retired from service for two reasons—cracking, due to overload, and failure of lower end, due to undercutting by stream. Latter failure can be prevented by proper design and installation. Results of detailed examination of individual culverts are given. During the life of culverts covered by these inspections, pipe were installed without much reference to relation between strength of pipe and height of fill for particular locations, but investigation in 1915 showed that older pipe were not strong enough and at various later periods stronger designs were used. Necessity for standardization of materials and manufacturing

conditions as well as of design, is indicated by the fact that two plants working under the same design produced pipe of considerably different strength. Greatest destructive force acting upon concrete pipe culverts was pressure of fill supported by pipe including effects of truck wheels and other super-loads. Three defects in installation which affect the serviceability and durability of the culverts were: (1) open joints between sections; (2) culverts laid on too flat a grade line so that pipes became more or less filled with mud; and (3) culverts installed with outlets subject to undermining by cutting back of stream channel. The latter two defects might occur with any type of culvert. A point not to be overlooked is that although certain culverts may have various defects, they may still be performing their major function. Marston's method of computing probable imposed loads on culverts is included, together with curves for facilitating such computations.—R. B. B. MOORMAN

Foundation problems and their solution. L. R. VITREBO. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 301-303.—A footing is a structural unit used to distribute wall or column loads to foundation materials. A spread footing distributes load directly to soil without use of any other intermediate structural members. Such footings are nearly always made of reinforced concrete to save in excavating, materials and weight of footing proper. Five classes of spread footings are: (1) wall footings, (2) independent column footings, (3) combined footings carrying more than one column, (4) cantilever footings and (5) raft or mat foundation. In ordinary type of building, that footing should be chosen in which live load bears highest percentage to dead load, and its area should be determined for total load at allowable soil pressure. Pressure of dead load per unit of area should be determined, and area of all other footings should be proportioned for dead load only, with this unit pressure. Independent spread footings are usually square or rectangular for practical reasons. Those with sloping tops contain less concrete than stepped footings, but. unless slope is flatter than 2 horizontal to 1 vertical, the top will require forms which offset any saving in concrete. Combined footings are simply inverted girders, or slabs receiving an upward pressure equal to carrying capacity of soil, throwing their end reactions to the columns which bear upon them. Cantilever footings are often resorted to when combined footings are expensive or impossible to use, that is, when it is necessary to make use of land close to property line and still not encroach upon adjoining property. Raft or mat foundations are used for soils of low bearing capacity. The foundation is then spread over whole area of building using either flat slab or beam and slab construction.—D. E. LARSON

Reinforced concrete and its hypotheses. FERNAND DUMAS. *Génie Civil*, Dec. 6 and 13, 1930, V. 97, No. 23-24, p. 561-564 and 589-593.—Reinforced concrete theory is based on a series of paradoxical results of inexact and incomplete experiments. Various official circulars make no effort to conceal the crude approximations. Research has concentrated on elaboration of detail. Yet how much more important for the design of a section is exact determination of coefficient $n = 10$ or 15, than slight variations in allowable stresses? Design, instead of seeking to establish actual stresses produced by forces acting on a certain member, attempts only "to prove sufficient safety of structure," according to the German authority, Mörsch. The weakness of this procedure is admitted in 1906 specifications, requiring that tensile strength of concrete be taken into account under certain conditions. But what to do in the case of hyperstatic structures? A study of deformation of reinforced concrete structural members is greatly neglected. Deformation measurements with Manet-Rabut apparatus are accurate only in rare cases of simple tension or simple compression. Deflection measurements of flexural members yield results widely diverging from computed design values. The author attempts to throw light on the actual agreement of fundamental hypotheses of design with the basic properties of reinforced concrete and to test application of

elastic theory and theory of strength of materials in this case. Reinforced concrete is a heterogeneous material in its constitution and its fabrication. Its three constituents are: steel, concrete in tension and concrete in compression. Of these steel is least variable and should be—yet is not—standard of comparison. Early experiments by Considére and Bach show that properties of concrete are greatly altered in presence of reinforcement. Is it correct to apply theory of elasticity to this heterogeneous combination? Does law of continuity hold in this case? It seems, that elastic theory furnishes us only with approximate indications, which are to be treated only as average values. Heterogeneity due to fabrication upsets elemental theory of strength of materials, whose laws deal with simple tension, compression, flexure and torsion, on condition that shear is equal to zero. The assumption is that *some transverse section remains plane*, identical with its original position and perpendicular to neutral axis during deformation. The author takes up in succession compression, tension, flexure, transverse deformation and torsion of reinforced concrete and comes to the conclusion that the above assumption is inexact for reinforced concrete and that results of this hypothesis necessarily disagree with actual conditions.—M. A. CORBIN

Formulae and curves for the calculation of members in reinforced concrete in bending. F. CAMPUS.—*Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—The formulae proposed permit making all bending calculations for ordinary members in reinforced concrete of rectangular or T section singly or doubly reinforced bending being eventually accompanied by compression or tension. In all these cases calculations are carried out by analogous formulae and the same coefficients of which values are given by five graphs. The simple manner in which the coefficients occur in the formulae shows clearly influence of various factors. These formulae can receive terms of adjustment to allow for compression in the ribs of T sections, and equally can be simplified to allow of rapid calculation. The formulae and curves are suitable for all values of coefficient of resistance and of elasticity of concrete and steel.—EDITIONS LA TECHNIQUE DES TRAVAUX

Calculation of rigid structures by the method of assumed static moments. J. RIEGER. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Method presented is called method of assumed static moments which consists of a geometric interpretation of equations provided by the theorem of Castigliano. A construction of several spans being given, it is always possible to divide it by the spans into several intermediate constructions for which conditions of deformation can be written as functions of assumed static moments with moment diagrams in relation to certain axes. These equations combined with static equations given the solution of the problem which is expressed in the general formulae by the form $M_m = \alpha_m A\ \beta_m B + \gamma_m C + \ldots \chi_m U + \varphi_m V + \xi_m Z$ in which the symbols indicate: M_m, moment in some joint of the construction given; $A, B, C, \ldots U, Y, Z$, certain functions of loads applied to the construction. $\alpha_m \beta_m \gamma_m \ldots \chi_m \varphi_m \xi_m$ being functions of the form of the construction studied. It is always easy to tabulate the functions $A, B, C, \ldots U, Y, Z$, and the coefficients $\alpha_m \beta_m \gamma_m \ldots \chi_m \varphi_m \xi_m$ to facilitate the use of the method.—EDITION LA TECHNIQUE DES TRAVAUX

Reinforcement of panels and slabs. H. LEITZ. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—The progress of the use of panels and slabs as elements carrying load in reinforced concrete structures necessitates extension of theory of reinforced concrete to calculation of reinforced walls subjected to forces acting in their own plane, combined with the study of reinforcement of slabs. Under heading 1 (uncracked concrete) the usual hypotheses can be used to calculate the tensions

in the concrete and steel as well as for the arrangement of the reinforcement. The case of pure shear always occasions difficulty notably when reinforcements have finite thickness. The calculations for the reinforcement of a wall must be based on the hypothesis of cracked concrete (heading 2). The simplest and most certain reinforcement comprises two families of reinforcements following the lines of equal stress which at once raises difficulties on account of the curvature of these lines. For this reason two parallel sheets of straight reinforcement are very often used, and applied in various ways. The principal difficulties arise with the shear stresses. We have to admit that the concrete may act as a compressed diagonal in a direction inclined at 45 degrees to the reinforcement but we must expect large deformations following lines of principal tension. In case of heavy shearing loads and variable applications, three layers of reinforcement are necessary. Just as a deflected sheet may be considered as a pile of thin sheets, the same consideration may be applied to the corners of slabs simply supported.—EDITIONS LA TECHNIQUE DES TRAVAUX

ROADS AND PAVEMENTS

Concrete pavements. D. J. GARLAND, *J. Inst. Eng.* (Australia), Oct., 1930, V. 2, No. 10, p. 396.—The various well known methods of estimating proper thickness of concrete roads are reviewed, including Goldbeck's simple formula $h = \sqrt{\frac{3P}{f}}$ where h = depth of slab in inches, P = load in lb. and f = safe tensile strength of concrete in lb. per sq. in., also Prof. Westergaard's more elaborate treatment. In actual practice, a standard thickness is usually decided upon and foundations prepared where necessary. Since engineers have better knowledge of thickness of macadam required for various conditions, experimental results of comparisons between the thickness of macadam required and of an equivalent concrete slab are discussed. The results state that (a) for a given load intensity of pressure under a macadam road is 8 times pressure under concrete slab of same thickness, and (b) area of distribution of pressure under a concrete road is at least four times as great as under a macadam road of same thickness. These areas are actual areas over which pressure is recorded and not equivalent or effective areas. Result (a) appears more reliable. Accepting this data and assuming conical distribution of pressure to the foundations it is shown that if h' = macadam thickness and h'' = thickness of equivalent concrete slab, $h' = \sqrt{8h''}$. For greater safety the factor may be taken as less, say, 4, when $h' = 2h''$. In an example it is proposed to substitute a 5-in. concrete slab and prepared sub-grade for a 12-in. macadam surface. If $h' = 2h''$ equi valent macadam thickness for concrete slab = 2x5 = 10 in. and thickness of sub-grade required = 12 — 10 = 2 in.—JOHN E. ADAMS

ARCHITECTURAL DESIGN

The architecture of concrete. BERESFORD PITE. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Consideration of effect of primary distinction in method between an architecture of stone or brickwork and an architecture of concrete is motive of this paper. The idea of internal adhesion belonging to material producing homogeneity without anxious care must be novel, and of nature of a relief to the constructor; its attainment has always been his ideal, but the repugnance to the employment of concealed tierods for cohesion in walling is always manifested by the consistent tendency to rely either on trabeated or arcuated lines. The new idea, as our brethren on the Continent have perceived, is revolutionary rather than evolutionary. It raises manifold questionings as to

due architectural expression, and necessarily also it involves reconsideration of methods in study of practice of design, with courses of training leading to its fulfillment. It would appear to be consequential, if we had not experience of antiquity to the contrary, that a fundamental constructive method must deflect architectural expression of construction from traditional motives. Such expression is at least one of the primary causes of any architecture, though its caricature as decoration may survive and invade other materials and methods. Today we are in the presence of a new process that is rapidly becoming general and therefore little apology is required for an attempt to discuss its manifestation in architecture and its effect upon our ideals. The subject is sketched under three heads: 1. The difference in constructive method and its expression in design. 2. The resulting architectural forms and the possibility and service of ornament. 3. The problem of the aesthetic use of concrete architecture.—EDITIONS LA TECHNIQUE DES TRAVAUX

Architecture and reinforced concrete. E. BALIS. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—So weak is our poor spirit—said Suger—that it attains to truth only through the medium of realities perceptible to the senses. Truth is the spirit and the chief element of architecture, realities being the forms of the art. We may distinguish true and false forms. An unfortunate tendency of our times is to consider details while slighting the generality. This is a point brought out indicating our conception of new architecture and the forms proper of reinforced concrete. Architecture is an art and therefore something more than a technique.—EDITIONS LA TECHNIQUE DES TRAVAUX

The architecture of concrete and reinforced concrete. A. POMPE. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—The aesthetics—still undetermined—of concrete and reinforced concrete are subject, like those of wood, brick and stone, to certain laws. These laws are themselves subject to the spirit of the time; they evolve in accordance with those material and immaterial conditions that govern the "directive" periods which follow on one another through history. That is to say, a "style" is far more an emanation from the spiritual and sentimental character peculiar to a given civilization, than it is the necessary and inescapable expression of the proper handling of a given material, the use of which happens to have been preponderant during that civilization. Style is an intermittent and periodic phenomenon, whereas the art of building is a permanent fact, though its value may vary. Style is expression: architecture is but a mask applied to building with more or less of expressiveness and truth. Wood, brick, stone, steel and reinforced concrete, each has its proper technique; that of rolled steel is a modern thing, and that of reinforced concrete is more recent still. In architecture steel has never properly succeeded, for a number of reasons. Reinforced concrete has only now entered upon a really active phase, and there is reason to believe, for other reasons, that this material will have an influence over the architecture of tomorrow much greater than that of its elder brother steel.—EDITIONS LA TECHNIQUE DES TRAVAUX

Four modes of construction in a single settlement or subdivision. *Betonwerk* (Germany), Dec. 7, 1930, V. 18, No. 49, p. 688.—Toward the end of year 1928 the Leipzig Fair Association presented a plan to the Sachsischen Arbeits and Wohlfahrtsministrium, to build four apartment buildings of 24 families each of steel, concrete, wood and brick respectively. The idea is to afford an opportunity to study each type of construction in a comparable manner. It is hoped that economical and technical phases of each class of construction may by this method be better observed. Each building is about 200 ft. long by 21 ft. wide and 3 stories high. The whole idea presents a building material exhibit in which many of building specialties can be seen. Each building is illustrated and described in detail. The entire enterprise is nearing

completion and is under direction of Rudolph Stegeman, Government Building Advisor, Leipsig. It is an experiment which up to this time has not been tried, and in due time the Leipsig Builders Fair will issue a complete report.—H. FRAUENFELDER

FIELD CONSTRUCTION

BRIDGES

Precast light weight concrete slabs solve bridge floor problem. *Concrete*, Jan., 1930, V. 37, No. 6, p. 15-16.—New type of bridge floor, consisting of large precast slabs of light-weight concrete welded to steel floor system, has been developed by Division of Bridges of City of Chicago. The Wabash Ave. bridge has slabs over the entire moveable part of the bridge floor, including roadway. Twenty-eight of largest size slabs, 102 sq. ft. in area, were required, twenty-eight 73 sq. ft. in area, and 56 smaller ones between street car tracks and rails. Thirty sidewalk slabs 98 sq. ft. in area and 2½ in. thick, were required. Roadway slabs have total thickness of 5¾ in. and are reinforced with steel bars in top and bottom, and stirrups. Sidewalk slabs, of light-weight concrete, are 2½ in. thick, and reinforced with layers of welded wire fabric, held 1 in. apart. Cement and aggregates employed were 1:1½:2½ mixture of Incor cement, No. 3 torpedo sand, and coarse haydite, with 4½ gal. water per sack of cement. Slabs were cast by aid of electric vibrating process that vibrated steel reinforcement. Molds were in horizontal position. Reinforcement was anchored firmly. Four holes were provided in each slab into which 1-in. pipe sleeves were fitted to facilitate handling, and later filled with mortar. Each slab was also anchored by U-bolts passing under stringers and up through holes in slabs where loose plates were held with nuts. Anchoring device removed after slabs were welded into place. Slabs were lifted into position by steam derrick equipped with two sets of cable spreaders fitted with hooks on each end. Final operation was welding of slabs to steel floor system, by means of ⅜-in. protruding steel plates.—C. BACHMANN

Winter concreting on a three arch bridge. RICHARD F. REY. *Eng. News Record*, Dec. 25, 1930, V. 105, No. 26, p. 1004-1005.—Continuous prosecution of concrete work on main-arch spans in severe winter weather and a nice procedure in handling expansion joints were employed in construction of Logan St. bridge in Lansing, Mich. The Logan St. Viaduct is 1,075 ft. long and has three river spans 61, 67, and 90 ft. long, 534-ft. of reinforced concrete viaduct, and 126-ft. of concrete-incased steel beam viaduct and earthfill approaches between retaining walls. Portions of bridge constructed in winter were housed in a framework covered outside with ship-lap siding sealed inside with building paper and roofed with tar paper. The housing provided ample space for building forms and handling concrete. Unit steam heaters kept enclosure warm. These were standard heater units such as are used for heating industrial and commercial buildings, instead of pipe coils or cast iron radiators. Outside temperatures varied from around freezing to 10° below zero, and inside temperatures were kept between 60 and 70° for first part of heating period and from 50 to 60° for last part. Concrete was made from aggregates heated by steam-pipe grids underneath stock piles and water heated by passing through old steam boiler. Temperature of concrete entering forms was between 60 and 80°. Vertical 1-in. expansion joints were carried across bridge over river piers and at 100-ft. intervals throughout viaduct portions. Butt joints were employed. Double columns and column girders were constructed throughout to eliminate any sliding expansion joints.—D. E. LARSON

BUILDINGS

The demolition of several reinforced concrete buildings at Brunn. R. BORTSCH. *Summary Reports*, First International Congress for Concrete

and Reinforced Concrete, Liege, 1930.—The machine factory of Brunn formerly Brand and Lhuillier disused for several years, was bought by the municipality which undertook in 1927 demolition of numerous buildings. By reason of existence of dwelling houses in immediate neighborhood, destruction of several halls and storied buildings in reinforced concrete of comparatively recent construction had to be undertaken with great care. The slabs were destroyed with a hammer. Ends of girders were cut with a pneumatic drill and reinforcement divided by an oxy-hydrogen flame. Frames of halls 13 meters high were overthrown in turn and cut up on the ground. Bases of columns were cut, then frames were overturned by hauling on cables with a windlass. Division of columns and girders of large dimensions was carried out after overturning by means of dynamite. For reasons of safety pieces to be destroyed were covered with hurdles held between metallic trellis work. Certain parts of buildings with high stories of 55 ft. were destroyed in one piece by dynamiting columns. Three months were taken in demolishing reinforced concrete buildings containing 12,000 cu. yds. Cost was 127,000 Belgian francs.—EDITIONS LA TECHNIQUE DES TRAVAUX

MISCELLANEOUS

How to save in concrete form work. A. B. MACMILLAN. *Concrete*, Jan., 1931, V. 38, No. 1, p. 35-40.—Second half of article on estimating labor and material quantities gives figures for definite areas for all units of form work. Hours of labor required are expressed as equivalent number of hours for one man. Lumber, other materials, and labor are each detailed. Time when each type of form may be removed is given.—C. BACHMANN

Concrete calendar. "Beton Kalender 1931." 1930, Wilhelm Ernst and Son, Berlin, 2 parts, 25th year, 1020 illustrations, R. M. 7.50.—Reviewed in *Bautechnik* (Germany), Sept. 19, 1930, V. 8, No. 41, p. 629.—This handbook for concrete and reinforced concrete construction is one of most common books and reference work for German contractors and concrete investigators. Two volumes are greatly enlarged and revised, especially chapters on slabs, tanks, arch bridges and girder bridges. Chapters on calculation of reinforced concrete cross-sections, solid floor construction and ground construction are new. New specifications for cement, mortars and concrete of several countries are given and great number of general tables are included. A. E. BEITLICH

New improved movable conveyors for cast concrete construction. RIEDIG. *Bautechnik* (Germany), Sept. 5, 1930, V. 8, No. 38, p. 567-8.—Great economy of movable conveyors for structural materials and their great field of application led more and more to their introduction in modern cast concrete construction. Two new patented conveyors are described with 66 and 44 tons per hour capacity. Materials are delivered to conveyor belt in first case by means of two screws and in the other case by means of a scraper. For concreting of quays, long walls or canals a new traveling concrete distributor is described handling 1400 cu. ft. per hour. A 2-yd. concrete mixer is mounted on base of crane. A number of minor improvements on travelers and chutes are illustrated.—A. E. BEITLICH

Crushed-stone plant builds profits by producing pre-mixed concrete. *Pit and Quarry*, Nov. 19, 1930, V. 21, No. 4, p. 56-58.—A new central-mixing plant has been erected in connection with crushing and screening portion of Hawthorne plant of Samuel Bracus Sons, Paterson, N. J. Eighteen reinforced-concrete storage bins of combined capacity of 5,000 tons and stock-piles assure a ready supply of aggregates. Two 3-compartment batcher bins are arranged side-by-side. Batching hopper of one bin can discharge dry mixes into transit-mix trucks or into a 3-cu. yd. stationary mixer, as desired. Mixer discharges

wet mixes into agitator trucks at one side. Other bin is for dry-batching stone, sand and cement, and it discharges into multi-batch trucks to be used in road construction. All proportioning is by weight. Sacked cement is received in truckloads and stored. Sacks are opened by hand and cement dumped through a grizzly in floor to conveyor which runs to a cement hopper at side of one batcher bin whence screw conveyor transfers the cement to weighing hopper. Firm operates ten dump-body and four transit-mix trucks.—A. J. Hoskin

A caisson foundation job. O. E. Mogensen. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 311-314.—The open-well type of caisson foundation, used extensively in the vicinity of St. Louis, is well illustrated by the foundations for the Missouri Portland Cement Company's new early strength Velo plant, built during 1927 and 1928. To ascertain practicability of this open-well method, it was decided to sink a concrete caisson to support the high concrete chimney, lined with fire brick at top. The chimney is 19 ft. in diameter, 220 ft. high, and weighs about 1,100 tons. The caisson which was 19 ft. 6 in. outside diameter, with a wall thickness of 3 ft., struck fire clay 42 ft. below the ground surface. The first section of caisson, cutting edge, was 10 ft. high, and was made from company's high early strength cement. The entire caisson was sunk quickly and without trouble. Other structures for which caisson foundations were used consisted of eight cement silos in clusters with interspace bins, each of the silos 32 ft. in diameter by 70 ft. high; four rock silos 35 ft. in diameter by 60 ft. high; and four clinker silos also 35 ft. in diameter by 60 ft. high. Materials to be stored in these silos weigh from 100 to 115 lb. per cu. ft. The three silo structures weigh, respectively, when filled, 32,620 tons, 16,640 tons, and 18,560 tons.—D. E. Larson

Placing concrete under water. Cayetano Lugo. *Ingenieria* (Mexico), Oct., 1930, V. 4, No. 10, p. 407.—Author contends that usual conception of action of the tube (tremie) in placing concrete under water is erroneous. He suggests careful attention to use of graded aggregates and of a number of tubes rather than one.—C. G. Clair and M. N. Clair

Roads and Pavements

New system of concrete paving. *Rds. and Rd. Constr.* (England), Jan. 1, 1931, V. 9, No. 97, p. 24.—A system of paving is described, in which large, unsightly cracks are replaced by invisible hair cracks in much greater numbers. Instead of every precaution being taken to provide easy sliding of the slab over the foundations as expansion or contraction takes place, an unreinforced wearing surface is suitably anchored to a reinforced under-slab, which is again anchored into the sub-soil. In case of a clay sub-soil, for example, foundation is dusted with fine ashes or sand, and gridded with trenches 4 to 6 in. deep at say, 7 ft. 6 in. centers. A slab of 3 in. or more, thickness is poured and reinforced with at least 0.5 per cent steel. The top surface of this is indented with specially shaped elliptical recesses, and is provided with vertical pins for anchoring the top layer of concrete, and gaging its thickness. These pins also are used for indicating position of indent forms, and for holding reinforcement clear of ground. Top slab is then poured on this sub-base, and through indents and anchors, is made to break up into small squares each separated from one another by minute hair cracks caused by excessive tension. The ribs in the foundation cause a wide distribution of pressures, and continuity is provided. Less care need be taken in curing with this method of construction.—John E. Adams

Shop Manufacture

Manufacturers like winter work. *Concrete Products*, Dec., 1930, V. 39, No. 6, p. 13.—A symposium of data from a large number of subscribers re-

garding the winter manufacture of concrete products shows that many manufacturers favor winter manufacture, at least on a reduced scale, for the purpose of holding their best men. It also allows them to accumulate stock, especially in case of block manufacturers, for an early spring building campaign. It is generally believed that the additional cost of products made in winter is negligible, although there may be some delay in the handling of frozen materials. The opinion is expressed by one burial vault manufacturer that winter is a better season for the burial vault business, and it is his belief that vaults cured in winter are of better quality.—E. S. HANSON

Profitable manufacture of concrete building units. FRED A. SAGER. *Concrete*, Jan., 1931, V. 38, No. 1, p. 17-20.—An illustration of the production ills of a large manufacturing concern are described and the prescribed remedial measures outlined. Interest to products industry in the example is possibility of reducing stocks carried, by smoothing out production curve with fluctuating delivery curve, by a careful control of a few major items of plant's product. As an application of method to the products business, the output for one year, based on the actual experience of a plant, is given in the first four columns of a table reproduced. The second column shows the number of the item in column (1) sold during the year. The third column converts amounts in column two to a common base. Fourth column shows production in "equivalent units" for each item, expressed as percentage of total production, a glance showing that the major production was in five items out of sixteen listed. By including in Group A all items over 5 per cent of total production, and in Group B all items under 5 per cent, we find 90.28 per cent of the production in five items of Group A and 9.79 per cent in 11 items of Group B. By study of production and stock, so far as five items of Group A are concerned, control of the major part of the output is accomplished and items in Group B can be handled by simple method as to stock carried and as a fill-in at convenient times, as to production. Minimum stock is determined as follows: First, the total stock carried shall be equal to the maximum month's sales for preceding year, or estimated maximum month's sales for coming year, if they are expected to vary materially from preceding year, to which is added one-half month's production. Second, stocks for each of major items, Group A, should be equal or nearly equal to maximum month's sales of that item. The stock for the items in Group B should be carried on average about one-half of an economical production quantity.—C. BACHMANN

Hollowspun concrete piles in the making. H. F. HEDDERICH. *Concrete Products*, Nov., 1930, V. 39, No. 5, p. 12-14.—Method followed by Westinghouse Electric & Mfg. Co., in making concrete piles is given in detail. Company has for past six years been producing concrete lighting and trolley posts by the centrifugal method and has recently applied same method to manufacture concrete piles. Piles are round and uniformly tapered for their entire length, increasing ¼ in. in diameter for each foot of length. The ultimate strength of the pile is governed by the compressive strength of the tip. The design is such that failure will occur at this point before the pile is stressed to its limit as a column. All of piles are provided with facilities for jetting. Concrete mix consists of one part cement to three parts of combined aggregate. Water is controlled to give concrete proper consistency for placing and spinning. Material used for both coarse and fine aggregate is very hard, highly dolomitic limestone with cubical fracture. It is very thoroughly washed during its preparation, and is received entirely free of dust. Mold is rotated at 400 r. p. m. for ten minutes. During the process of spinning, the solid particles (the aggregate and cement) are driven outward by centrifugal force and uniformly compacted against the inside surface of the mold and around the reinforcing. This brings all the entrapped air, a large amount of water, and some of the finer aggregate and cement, to center. A hole is formed throughout the length of the column by this action, and as the spinning continues most of the fine solids are packed around periphery of this hole.—E. S. HANSEN

Materials

Admixtures

The chemistry of Rhenish trass. Heinrich Hart. *Tonind. Ztg.* (Germany). Jan. 15, 19, 1931, V. 55, No. 5, 6, pp. 65-6, 84-6. By means of solutions of benzene in bromoform, trass from different places along the Rhine was separated into several fractions. Trass is of variable mineralogical composition and seems to be an alkali aluminosilicate in varying stages of hydrolysis. —F. O. Anderegg

Cement admixtures, their action and absorbing power. P. Mecke. *Tonind. Ztg.* (Germany). Jan. 8, 1931, V. 55, No. 3, p. 33-6.—A few tests, made with rather large amounts of water glass, oleic acid or other water repellent substances, did not yield very encouraging results.—F. O. Anderegg

Aggregates

Specifications for sand, gravel and crushed stone. *Tonind. Ztg.* (Germany), Jan. 5, 1931, V. 55, No. 2, p. 21-2.—Using woven wire sieves up to 1 mm. and round openings for separating larger sizes, separations of aggregates are made at openings: .0024, .0035, .0079, .0236, .0394, .118, .276, 3/8, 5/8, 3/4, 1 1/4, 2, 2 3/8 and 2 3/4 in. For railroad ballast separation is made at 3/8, 3/4, 1 1/4 and 2 3/8 in.—F. O. Anderegg

Tentative standard specifications for gradation of sand, gravel and broken stones. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 37-8.—Report is given of third meeting of committee for standardization of aggregate grain sizes, held on Oct. 31, 1930 in Berlin (Germany). Specifications cover natural sands and gravels, broken rocks, concrete aggregates and materials for railway roadbed construction work. New fixed definitions for certain grain sizes are proposed.—A. E. Beitlich

Thermosit compared with natural pumice. Heinrich Hart. *Betonwerk* (Germany), Aug. 3, 1930, V. 18, No. 31, p. 432.—Chemical analysis, comparative porosity, weight, capillarity and strength of both natural pumice and artificial pumice, "Thermosit" are discussed, and the use of these materials as a light weight aggregate in actual work described. The article is fully illustrated with reproductions of photographs and tables of tests.—Herman Frauenfelder

The application of protective mortar coatings containing metal aggregates. Georges Dupont. *Ciment* (France), Dec., 1930, V. 35, No. 12, p. 462-74.—Concrete exposed to sea water and other conditions where it is subjected to chemical or frost attack or to erosion by flowing water should receive an impermeable and durable protective coating. Metallic aggregates are often suitable for making mortars with cement for this purpose.—F. O. Anderegg

Inert aggregates and the mechanical properties of concrete. R. Dutron. *Rev. des materiaux construction trav. publics*, July to December, 1930, No. 250 to 255.—Article in six instalments emphasizes importance of nature, shape and grading of inert aggregates. Highest compressive strengths are obtained with concretes using river sand and gravel, rounded in shape and well graded. The elastic coefficient being a direct function of compression strength, the same applies in this connection. The reverse order prevails, when results of tensile and flexural strength are considered. The rounded aggregates of river origin yield lowest tensile strengths. Ratio of tensile to compressive strength of concrete varies with age of concrete and with aggre-

gate used. It is highest for crushed aggregate and lowest for river sand and gravel. This ratio varies from 1/10 to 1/20, when compressive strength is tested on 7.9 in. cubes. Shear is a linear function of compressive strength. Its ratio to the latter varies from 2/10 to 3.5/10, when tested on cubes with cross section of 62.0 sq. in. Impact strength is greatly affected by the nature of inert aggregates, the rounded river sand and gravel being most brittle.—M. A. CORBIN

Laboratory studies in the prevention of segregation. A. T. GOLDBECK. *Crushed Stone J.*, Nov., 1930, V. 6, No. 11, p. 3-7.—The theory of segregation is stated as follows: When aggregate, falling in a single stream, piles up in the form of a cone, surface voids entrap pieces of smaller diameter, therefore causing pieces of larger diameter to roll to the outside. Studies were made to develop a method to prevent piling up of material in the form of a cone. A model bin and railroad car were constructed to scale of one inch to the foot and stone screenings approximately the same scale were used for aggregate. Ten possible methods of preventing segregation were investigated. Of these, two gave promise; the single balanced gate and the double balanced gate. The single balanced gate is recommended because of its simplicity. It is a hand operated swinging plate pivoted under the center of the stream at a point one-third of the way down from the top. This distributes the aggregate in a horizontal layer laterally across the car, thus preventing segregation.—J. E. GRAY

High quality aggregates and value of concrete. PAUL HERTEL. *Zement* (Germany), Nov. 13, 20, 27, Dec. 4, 1930, V. 19, No. 46, 47, 48, 49, p. 1087-90, 1117-21, 1141-4, 1167-9.—Investigations were made as to how quality and costs of concrete can be improved by changing gradation of aggregates according to sieve curves now in practice. Following methods are discussed: (1) Fuller curve takes aggregates and cement into consideration, (2) curve by Herrmann is similar to Fuller curve but gives a greater number of sizes between 0.12 and 0.47 in. and does not consider cement content, (3) Graf emphasizes importance of fine aggregates and gives a favorable mortar curve, (4) Gruen established a void-volume curve. He determines volume of voids of aggregates by filling a cylinder with coarse particles and water and then replacing water by fine aggregate. (5) Otzen derived an ideal curve, similar to Fuller curve which shows directly grain composition of aggregates for certain mixtures, or cement contents per cu. ft. Great number of experiments were made to study effect of improving aggregates by means of above described curves on yield, consistency, weight per cu. ft., compressive strength, flexural strength and water permeability. One blast furnace slag cement and one high alumina cement were used for these tests. In all cases 18.7 lbs. cement were used for 1 cu. ft. of concrete and consistency of all mixtures was plastic. Results show clearly that properties of concrete are greatly improved by such methods, especially water impermeability. Costs of concrete are in general about 20 per cent higher when aggregates are treated in such manners.—A. E. BEITLICH

Control and improvement of the granular composition of sand, pit gravel, and fluvial deposits used in the manufacture of concrete. A. JANOUSEK. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—River deposits excavated for use in concrete have only exceptionally the composition required. To control this composition, it is essential to carry out a grading analysis, which should be executed with all possible care. Attention should be paid to following points: (1) Diameter and geometric shape of grains, in relation to strength. (2) Surface area of single grains, and of total of grains collectively, in relation to strength. (3) Proportion of grains of any one diameter, and relation between various diameters. (4) Means of employing these results for improving granular composition of material. A common in-

direct procedure consists of sieving mixture in a series of sieves, thus measuring the granular composition of a given quantity of material. The surface area of the grains can be determined, although only approximately, by either an experimental or a mathematical method, both of which are based on results of sieve analysis. To use the results of these investigations rationally and economically, it is necessary to organize continuous control on the building site. In addition it is desirable to control mixing of concrete, and to mechanize operations as much as possible with object of eliminating personal influence of incompetent workers. There is at present no sufficiently accurate experimental method for determination of surface area of gravel, but directions are given for calculation of this quantity, a knowledge of which is most important, particularly in connection with tensile strength. In addition the question of international unification of methods of control has been studied, and various propositions elaborated. The essential requirement is a series of sieves having circular holes, .039, .118, .275, .590 and 1.180 in. or .039, .078, .197, .394 and .787 in. in diameter. The natural limits of application of the grading modulus are dealt with, and finally a simple method of comparison of grading analysis curves is suggested for application in the correction of natural grading.

CEMENT

Tube mill grinding. BELLWINCKEL. *Zement* (Germany), Dec. 4, 1930, V. 19, No. 49, p. 1161-3.—Author attacks statements made by A. B. Helbig in previous article (*Zement* (Germany), Sept. 9, 1930, V. 19, No. 37, p. 870-3; JOURNAL A. C. I., Dec. 1930, V. 2, No. 4, *Abstracts*, p. 97), on superiority of tube mills with air separators over ordinary tube mill type. For an economic performance of a tube mill without air separator, the following points must be taken into consideration: (1) Entire length of mill must be divided into 3 or 4 sections, (2) form and weight of steel balls must correspond with increasing fineness of material, (3) separation of coarsest particles by screens and (4) sufficient aeration and cooling of entire mill. These points are discussed for raw mix, coal and cement.—A. E. BEITLICH

Tube mill grinding. A. B. HELBIG. *Zement* (Germany), Dec. 25, 1930, V. 19, No. 52, p. 1234-5.—In reply to article by Bellwinckel (*Zement* (Germany) Dec. 4, 1930, V. 19, No. 49, p. 1161-3), author again emphasizes advantages of air separator installations in tube mills and cites a number of American experiences.—A. E. BEITLICH

Tricalciumsilicate. ENRST JAENECKE. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 26.—After studying paper by L. T. Brownmiller and R. H. Bogue on "The X-ray method applied to a study of the constitution of portland cements," author admits existence of tricalciumsilicate, contrary to his former opinion. Furthermore he points out, that his compound jaeneckeit: $8CaO.Al_2O_3.2SiO_2$ can exist as found by X-ray measurements. He explains necessity of work with petrographic microscope and X-ray in portland cement clinker constitution problem.—A. E. BEITLICH

Cement and concrete in the graphic four-component parallelogram. M. SPINDEL. *Zement* (Germany), Dec. 18, 1930, V. 19, No. 51, p. 1200-5—A four-component diagram in form of a parallelogram is explained and its application advised for proportioning of cement mixtures, especially for high early strength cement. Allowable limit for lime content for manufacture of best cement, as calculated by Kuhl, Jaenecke, Guttmann and Gille are plotted in diagram and compared.—A. E. BEITLICH

Acceptance and control tests for cements. QUIRINO SESTINI. *Ostr. Bauzeitung* (Austria), Dec. 13, 1930, V. 6, No. 50, p. 810-1.—Author claims that ordinary tests do not give a true picture of all properties of cement. Behavior with different aggregates and retarding or preserving agents are not

considered. Opinions of A. J. Poole and C. R. Platzmann on subject of cement testing are discussed. An empirical formula for valuation of cement is derived which gives a relation between compressive strength C and tensile strength T. $R = \frac{T \times 10 + C}{2}$ R is quality factor. (*cf. L'Industria Italiana del Cemento* (Italy), July, 1930.)—A. E. BEITLICH

Determination of soluble silica in puzzolan cements. G. BAIRE. *Chimie et Industrie* (France), March, 1930, V. 24, special number, p. 298-300.—A method is given for determination of soluble silica in puzzolan and mixtures of portland cement and puzzolan or trass. Sample of 1.0 gram is treated with 100 cc. cold water and 25 cc. hydrochloric acid (1.1 per cent). Residue is filtered after gentle heating, washed with hot water and dried. Then it is treated for 20 hr. in the cold and 4 hr. at 122 to 150° F. with 100 cc. of a solution of potassium hydroxide (20 per cent). Precipitate is washed and ignited, treated with sodium carbonate and analysis is then continued as usual.—A. E. BEITLICH

Protective coatings for cement and concrete. *Zeitschr. Ostr. Ingenieur und Architekten Vereins* (Austria), Nov. 21, 1930, V. 82, No. 47-48, p. 408-9.—Principle of most protective materials is formation of an inorganic coating which is more weather resistant and under certain conditions even harder than concrete surface. Fluorides, especially magnesium and zinc fluorides, are most important and effective when an excess of lime is present in cement. Of similar effect are silicate coatings on which a second protective coating is advisable. Silicate esters are used for same purpose lately. Coatings may be white or colored with inorganic pigments. Hardening process of these materials is in general very slowly. Coatings can be made which resist temperatures up to 1100° F. Coatings do not destroy natural porosity of concrete surface.—A. E. BEITLICH

A new method for the determination of consistency of cement mixtures. KARL E. DORSCH. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 26-8.—Inaccuracy of Vicat method for determination of normal consistency of cement-water mixtures led author to design new apparatus which gives more accurate results without use or waste of much cement. Procedure is as follows: 100 g. cement is mixed for 3 minutes with 28 per cent water and then filled into small conical steel cylinder open at top and bottom. (Lower opening is smaller than top opening.) Cylinder with cement is then dropped between two vertical steel rods of special support which has a stop near bottom. When cylinder hits stop a small amount of cement will emerge from bottom opening. Cement which leaves cylinder after 3 runs is collected and weighed in small porcelain crucible. Table shows normal consistency calculated from weights of cement. Method was found to be highly accurate for various cements. Dimensions and drawings of apparatus are given.—A. E. BEITLICH

Temperature and humidity control in cement testing. H. S. MATTIMORE. *Eng. News Record.* Jan. 1, 1931, V. 106, No. 1, p. 36.—Product termed "high-early-strength cement," is more sensitive to temperature and humidity conditions during testing than cement produced several years ago. Specifications allow a tolerance of plus or minus 5 per cent. In some cases this is too broad, as conditions have been experienced in testing high-early-strength cement where a maintained temperature of 65° F. resulted in rejection on strength requirements, whereas these requirements were met when a temperature of 70° or over was maintained. Standard specifications require that relative humidity shall not be less than 90 per cent in moist closet during storage of strength specimens. In Pennsylvania department of highways testing laboratory the special moist air cabinet is constructed with slate interior, 1 in. of cork insulation and steel exterior. Humidity is maintained from 95 to 98 per cent by running water flowing from perforated pipes in each

section down the sides of brass mesh screen mounted ⅜ in. from the side walls. Temperature of water is regulated in temperature control valves prior to entering the cabinet. Temperature records over many weeks indicate a maximum variation of 2°.—D. E. Larson

Comparative investigation of effect of chlorides of calcium, barium and beryllium on setting process and strength of normal portland cement and portland cement without gypsum. K. Fill. *Zement* (Germany), Dec. 11, 18, 1930, V. 19, No. 50-51, p. 1178-84, 1206-9.—One portland cement clinker and one portland cement were mixed with aqueous solutions of calcium chloride, barium chloride and beryllium chloride and changes in setting time, compressive and tensile strength under different storage conditions were studied. Concentrations of solutions were 3, 2, 1, ½, 1/5 and 1/10 molar. Heat tones of reactions of cement and clinker with above solutions were measured and recorded in special insulated apparatus. Effect of these electrolytes on cement and clinker were considerably different, especially in case of $BeCl_2$ solutions. Strength of clinker is only slightly affected, while strength of cement is greatly reduced by $BeCl_2$. Calcium and barium chlorides improve in general strength of clinker and have similar effect as gypsum on setting time. Effect of these salts on heat tones is illustrated in several curves. Work was carried out in the Institute for Mineralogy of University of Frankfurt a. M. (Germany).—A. E. Beitlich

Impermeability and permanence of cements. Edmond Marcotte. *Ciment* (France), Dec., 1930, Jan., 1931, V. 35, No. 12, p. 476-82; V. 36, No. 1, p. 6-12.—The leaking of masonry walls is a subject of much concern and the attack of aggressive waters on concrete is to be connected with penetration of moisture into the concrete body. A complete investigation of the problem would require a very large number of experiments. After discussing briefly the properties of the several French cements the classic work of Michaelis on admixtures is reviewed in detail. The superior results obtained with European pozzolanic materials, especially in increasing resistance to sea water, is emphasized. A cement is now available made by grinding portland cement clinker with *gaize*, a pozzolan found near Paris and containing about 33 per cent alkali soluble silica.—F. O. Anderegg

Reconstruction of cement plant in Rodaun (Austria) *Ostr. Bauzeitung* (Austria), Dec. 20, 1930, V. 6, No. 51, p. 828-30.—New Quarry for raw materials was added to plant. Aerial ropeway delivers material to crushers. After passing dryers raw material enters 2 modern three-compartment mills directly driven by high speed motors and provided with table feeders. Material of any desired fineness can be obtained. Raw mix bins have capacity of 2640 tons. One rotary kiln, designed by Fellner and Ziegler, Frankfurt, is 164 ft. long and 9.8 ft. in diameter; it has an enlarged calcination zone. Kiln is provided with clinker cooler. Waste heat boiler system furnishes necessary electric energy. Gases from kiln and dryers are purified by electric dust precipitator. Entire coal mill was rebuilt and new tube mills installed. Plant manufacturers portland cement, high early strength cement and iron portland cement.—A. E. Beitlich

Special carfloat used to distribute bulk cement. Morris Kind. *Eng. News Record*, Jan. 15, 1931, V. 105, No. 3, p. 111-112.—Bulk-cement delivery in New York City is complicated by fact that while most of cement is shipped from mills by railway, ultimate delivery with but a few exceptions must be by water. To secure quick, safe, economical delivery, bulk-cement cars and float have been constructed and used successfully. Cement is discharged from cars by gravity to a conveyor on the boat and then pumped to shore. There is no loss of cement and no dust. The float is equipped with a Diesel engine, generator, and compressor, and can handle 225 bbl. per hr. with total capacity of 3,500 bbl.—Glenn Murphy

Special and fused cements—two Swedish products. VICTOR BAHRNER. *Teknisk Tidskrift* (Sweden), Jan. 3, 1931, p. 9-11.—These two types of cement that have been used in Sweden for several years, are made of almost same parts. Fused cement is produced as a melting substance. Compressive strength is very high, shown by following table summarized from several charts and diagrams:

	Compressive Strength in Lb. Per Sq. In. After				
	1 day	2 days	7 days	4 weeks	9 weeks
Melt cement	4260	5350	6130	6760	7460
Special cement	1570	2350	3560	4840	5270

The mix was 1:2:4 and the water coefficient 0.6. The time of setting is found to be very short, so the forms can be taken down and reused frequently. The fused cement heats up after pouring. Therefore concrete buildings can be built in freezing weather without being inclosed and heated. Several concrete houses have been constructed during the winters in Stockholm with excellent result. Table gives proportion of fused cement for different temperatures and thicknesses of concrete. It is necessary to keep the concrete from freezing 24 hours. Fused cement can not be mixed with portland cement or lime which will cause immediate set with low strength. The special cement can be mixed in same proportions as portland cement and fused cement concrete can not be made richer than 680 lb. per cu. yd. concrete. It should not be used if the temperature is more than 90° F. As a conclusion it may be said that special and particularly fused cement is suitable for all kinds of concrete construction where high compressive stresses and short construction time are required in freezing weather.—ODD ALBERT

Pre-determination of the composition of the concrete necessary to attain a given compressive strength. R. B. YOUNG. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Method described has been widely used in the United States and Canada. It is based on Abram's water-cement-ratio-strength relationship and the soundness of this law for practical work is indicated. Details of method are outlined and typical data presented. Extensive references to original sources of information are included.—EDITORS N. I. A. T. M.

The degree of lime saturation. HESS. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 28-32.—Degree of lime saturation (S) is described as relation between actual lime content and theoretically possible amount of lime in a clinker: $S = \frac{CaO}{2.8\,SiO_2 + 1.65\,Al_2O_3\,0.7 + Fe_2O_3}$. Replacement of hydraulic modulus in German Standard Specifications for Portland Cement by degree of lime saturation is proposed. Advantages of this new index are characterized and its application for valuation of clinker is clearly illustrated. Index can be easily demonstrated in graphs. Kuhl's method for use of this index is criticised and several improvements are suggested.—A. E. BEITLICH

Effect of storage conditions on the properties of cement. D. A. G. REID. *Concrete Constr. Eng.* (England), Feb., 1931, V. 26, No. 2, p. 155-159.—Investigation deals with effect of storage conditions on the rate of hardening of cements, particularly rapid-hardening cements. Factors investigated are: type of cement (normal portland, rapid-hardening portland, and aluminous); type of container (jute sack, four-ply paper sack, wooden keg, and metal drum); condition of storage (closed shed at normal temperature, cold storage, and oven storage) and period of storage (from 3 mo. to 2 yr). Conditions selected to represent what might actually occur in practice. General conclusions: (1) Loss on ignition increased with storage for all types of cement tested and all containers except the metal drum. (2) Appearance—after severe types of storage (jute and paper sacks and storage in shed) cement appeared coarser to the touch and in some cases air-set lumps were formed. (3) Water requirements for standard consistence rose steadily with increasing

loss by ignition. (4) Fineness—no change except due to air-set lumps. (5) Setting time—not always affected in the same manner or to the same extent. (6) Specific gravity decreased as loss by ignition increased. (7) Decrease in rate of attaining strength.—Joseph Marin

Properties of Concrete

Influence of proportioning of mix and water addition on mortar compressive strength of three cements of different values. Erich Schmidt. *Zement* (Germany), Dec. 18 and 25, 1930, V. 19, No. 51-52, p. 1213-6, 1235-8.—In two extensive series of tests were studied influence of mix (proportions from 1:3 to 1:24) and influence of mixing water (from 4½ to 12 per cent) on mortar strength of one normal portland cement, one high early strength cement and one very high early strength cement (Zenith cement) with river sand. Curves for mortar strength development were in relatively close agreement with those from normal standard tests. Addition of water shows different effect according to age of specimen or kind of cement.—A. E. Beitlich

Watertight brick masonry. F. O. Anderegg. *Contract Record Eng. Rev.*, Nov. 26, 1930, V. 44, No. 48, p. 1476.—In connection with study of watertightness of brick masonry which included tests of cement mortars it was found that ideal grading of sand for mortar is one of uniform increase in amount with size of sieve opening using a standard series of sieves whose mesh sizes differ by a constant factor of 2, e. g. 100, 48, 28, 14, 8, etc. The amount passing a given sieve and retained on the next smaller should be about 1.25 times that retained on next smaller size. For good results brick must have the right range of absorption and a proper surface to bond well with mortar. Cement and lime used in mortar must be (1) suitably plastic to work well under the trowel, (2) adhere very tightly to brick, (3) be sufficiently flexible to take up buffets of wind even in tower buildings, (4) be watertight and (5) be reasonable in price.—G. M. Williams

Recent improvements in making concrete. H. A. La Rue. *Canadian Eng.*, Jan. 20, 1931, V. 60, No. 3, p. 16.—Basic idea underlying most methods of proportioning concrete is that a dense mixture of cement, sand and stone is necessary and that the denser the mixture, the stronger the resulting concrete that is obtained. Various methods are employed in the attempt to attain this maximum density. The so-called void method involves the use of enough cement to fill the voids in the sand to make a mortar and then sufficient mortar to fill the voids in the stone. The amount of cement is usually in excess of that required to fill voids in the sand. The method of mechanical analysis involves a sieve analysis of the aggregate and the addition or elimination of certain sized materials so grading of aggregate will conform to an established grading curve. Account must be taken of the fact that the volume of fine aggregate is influenced by its water content so that to insure the proper amount of this size of material account must be taken of bulking due to presence of moisture which will alter its apparent volume. To produce more uniform concrete it has been established that aggregate quantities should be weighed rather than measured by volume. It is of greatest importance in obtaining high strength concrete to keep the mixing water to the minimum necessary to furnish a workable mix. Sufficient water must be used to result in a plastic workable mix but this necessary amount should not be exceeded.—G. M. Williams

Action of aggressive waters on concrete. Hugo Vierheller. *Bautenschutz* (Germany), 1930, V. 1, No. 2, p. 33-7.—Corrosive action of aggressive waters on concrete may be either chemical, chemical and physical or only physical in nature. These factors must be considered when a concrete is judged

for its suitability for certain purposes. In the first case substances, which are dissolved in water, react with cement portion of concrete and either dissolve or weaken such portions thus changing structure and strength of concrete. Agents, which act in this manner are inorganic acids, some organic acids and acid salts. Protective coatings or drainage of water are advisable. Example for second case is crystallization of new compounds formed by chemical reactions in interior of concrete with considerable increase of volume. Latter fact destroys interior structure and leads to softening of concrete. Pure physical action of water on concrete can be found in cases where water is taken up by capillary action and this water generates osmotic or crystallization pressure. This process can appear without any chemical reaction and takes place in concrete of improper density. Structures only partly immersed in water are most likely to be affected in this way. Action of frost falls in this class. Making of dense concrete with sufficient impermeability is chief preventive measure. Directions are given for systematic investigation of different cements and concrete mixtures and of their stability in corrosive waters.—A. E. BEITLICH

Resistance of concrete pipes to corrosion by water. J. O. ROOS AF HJELMASTER. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—The paper comprises the investigation of typical cases of concrete pipe disintegration in Sweden, laboratory tests of the action of water with aggressive carbon dioxide on concrete pipes of different composition, and the application of a new laboratory method for the determination of the dissolving action of different kinds of water percolating through various kinds of cement.—EDITORS N. I. A. T. M.

Variations of the compressive strength of concrete within the water-cement ratio law. IRA L. COLLIER. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 731-741.—Three different series of tests, covering 450 specimens, were performed to determine how strength of concrete is affected by variation in consistency of mix, and in proportion and grading of sand. Water-cement ratio was varied from 0.6 to 1.4, slump from 1 to 9 in., and percentage of sand from 20 to 80. The cylinders were all tested at 7 days. The tests demonstrated that if water-cement ratio of concrete is held constant, and sand and gravel are in the usual proportions of 1:2, the compressive strength decreases as the slump increases, and decreases as the fineness modulus of sand is increased.—GLENN MURPHY

Mortars and concretes of mixed cements. F. FERRARI. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—The object of this study is to demonstrate relationship between the mechanical (crushing) strength of standard mortar and of concrete of determined composition. Mortars and concretes having as a basis binary hydraulic mixtures (portland cement with other substances, pozzuolanic or inert), possess, at same age, very different strengths, depending principally upon nature and percentage of material added to portland cement.—EDITORS N. I. A. T. M.

Volume change of concrete. C. H. SCHOLER AND E. R. DAWLEY. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 751-766.—This paper treats initial expansion or contraction of concrete during hardening period as well as volume changes after specimen has hardened. Changes in length were measured by an optical comparator consisting of two parallel microscopes. The distance between them was determined by an interferometer reading to 0.00005 in. Readings were taken on pieces of glass tubing inserted in the specimens 20 in. apart. In order to reduce pressure of forms against concrete during setting period, forms were lined with soft rubber slabs. It was found that leaky forms caused a rapid shrinkage until set. This was followed by an expansion for about 24 hr., and then a slow, steady shrinkage for an indefinite period. A water-tight form will eliminate the first shrinkage. It was found that character

of aggregate had practically no influence on volume change. Lean mixes showed slightly less change than rich mixes. Mixes studied were more nearly like pavement concrete than like that used in reinforced building construction. Probably the latter would show the greater shrinkage.—GLENN MURPHY

The elastic behavior of concrete—Uber das elastiche Verhalten von Beton. HIROHIKO YOSHIDA. Verlag von Julius Springer, Berlin, 1930, 114 p.—Work was carried out under direction of E. Probst, Technischen Hochschule, Karlsruhe. Methods are given for determining Poisson's ratio for different types of concrete under static loading, as well as effect of various factors such as changes in stress, age of concrete, water cement ratio, mix, etc. The second part deals with the results of a study of application of frequently repeated load, and gives effect of repeated loads on elastic properties. The last section takes up the elastic behavior of concrete and covers elastic afterworking, elastic potential, and a study of velocity of propagation of load waves in concrete. Conclusions of the author include: (1) The value of μ (Poisson's ratio) for concrete decreases with increase in tension. (2) μ for concrete 1:6 mix under a tension between 142.5 to 570 lb. per sq. in. and 142.5 to 712.5 lb. per sq. in. is about 7. With a 1:10 mix μ for the same tension is about 5.5 to 6. (3) The value of μ increases with repeated load. (4) The relation between value of μ, and the tension, and also the relation between the elastic modulus and tension change with repeated load. (5) The elastic behavior with repeated load is related to the afore mentioned change.—H. G. FISK

Investigation into the strength of mortar and concrete for use in large structures and for the manufacture of cement products. O. GRAF. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—The knowledge requisite for the production of mortar and concrete possessing the greatest resistance to crushing, bending and wear, with great impermeability and the minimum shrinkage and expansion, is, for practical purposes, capable of simple expression. The paper is developed on these lines, while in addition, the factors requiring attention in measuring and working the ingredients are briefly dealt with.—EDITORS N. I. A. T. M.

Cement, concrete and reinforced concrete. Laboratory tests, and control and practice on the building site. A. HASCH. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—An attempt is made to deal briefly, from the present day standpoint, with the relative merits of ordinary and high-strength mortars and concrete, as well as with the tests to which these materials should be subjected in the laboratory and on the building site. The essential point is the organization of control tests on the site, combined with an extension of the laboratory tests, especially on the chemical side, since samples taken before the commencement of building operations have not the slightest value. Reference is made to the statistic (theory of probability) treatment of the results of static tests.—EDITORS N. I. A. T. M.

Flow of concrete under sustained compressive stress. R. E. DAVIS AND H. E. DAVIS. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 707-730.—Data are presented from seven series of tests, starting in 1925, and dealing with 215 specimens. The tests were designed to show how time-flow is influenced by richness of mix, water-cement ratio, character and gradation of aggregate, age at time of loading, magnitude of stress, variation in moisture conditions, length of period of sustained stress, reinforcement, and intermittent loading. In addition, the effects of flow upon strength and modulus of elasticity are studied. Aside from earlier tests, flow was measured over a 10 in. gage length. It was found that rate of flow decreases as time increases. Amount of flow was greater for concretes of a lean mix, with high water-cement ratio, containing aggregates with a small fineness modulus. A high applied stress and air storage also increased flow. Rate of unit stress to total unit deformation was decreased by early loading and air storage, and decreased at a decreasing rate

with increase in time. Sandstone and basalt concretes showed greatest flow, and limestone concrete the least. Quartz, granite, and gravel concretes gave intermediate values. The flow for reinforced specimens was much less as the steel took most of load. Effect of cyclic repetition of stress upon flow is not unlike that for steady loading. The modulus of elasticity of concrete which has been subjected to a sustained stress is higher than that for same quality of concrete not previously stressed. Apparently the compressive strength is not affected. Modulus of elasticity at time of loading is not a criterion of flow.—GLENN MURPHY

Research on the variation of the modulus of elasticity under compression with the composition, fluidity, age and strength of concrete. R. DUTRON. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Modulus of elasticity of concrete, E, is a function of strength, i. e., it depends implicitly on all factors which affect strength: Proportion of cement, nature and grading of inert material, fluidity, and age of the concrete. Value of E may be determined as a function of the crushing strength R of concrete by formula $E = KR^m$; E corresponds to the deformation of concrete under a load equal to three-tenths its breaking load under compression, K and m are two constants which assume different values on the one hand for concrete containing ballast and powdered materials, and on other, for all concretes containing sand.—EDITORS N. I. A. T. M.

The compactness of concrete and its resistance to chemical action. A. POULSEN. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Even the best concrete is destroyed by the reaction of its free lime with the magnesium sulphate contained in sea water. On the other hand, rich mixtures soon show cracks of their own accord. The application of a protective coating to large masses of concrete employed in marine work is, of course, impossible. To neutralize the excess lime it is necessary to add to the cement, pozzuolana containing in sufficient quantity the necessary hydraulic constituents (e. g. SiO_2 soluble in alkalis). The cement with hydraulic admixtures thus obtained should be submitted to laboratory tests. In Denmark, the Danish diatomaceous earth, Mo Ler, which contains about 60 per cent of soluble SiO_2, has been used with considerable success for the past 20 years.—EDITORS N. I. A. T. M.

Method of disintegrating hardened concrete for the determination of the original ingredients. R. LOMAN. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—The object of the work was discovery of a method of determining original ingredients of hardened concrete. It is possible to disintegrate the concrete satisfactorily without smashing up the aggregate. This is done by heating for a time to 800-900 deg. C., and then cooling by suddenly quenching in water. Aggregate is separated from cement and can be sieved; it is almost completely recovered, but has generally become a little finer, owing to ignition and embrittlement on quenching. This increase in fineness is revealed by sieving. Proportion of cement can be estimated by various methods. Experiment has proved, however, that most rapid method, and that which gives most reliable results, consists in heating to 800-900 deg. C., (which removes combined water and carbon dioxide), and then cooling in a space free from water vapor and CO_2. Weight obtained is that of original cement, less its loss on ignition. The method is of ample accuracy for technical work.—EDITORS N. I. A. T. M.

Further studies on the workability of concrete. W. F. PURRINGTON AND H. C. LORING. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 654-667.—This paper is a continuation of a previous investigation of workability of concrete mixtures by measuring power consumed in mixing concrete. Tests were run with a 390 lb. charge in a vertical-axis type mixer at speeds of 24, 30, 35, and 44 r. p. m. Readings were taken 5 min. after water was added. Actual power

consumption was measured by a prony brake. Mixes were designed for 2,000, 3,000, and 4,000 lb. per sq. in. at 28 days. Data tend to show there is an optimum water-cement ratio at which maximum workability of a concrete is obtained. Above and below this ratio a concrete is produced which tends to increase power consumption due in one case to stickiness of particles, and in other to friction of under-lubricated grains. Different brands of cements do not show consistent relations to power consumption when studied over a long period of time. The addition of calcium chloride affects the workability of different cements differently.—GLENN MURPHY

Strength and resistance to sulfate waters of concrete cured in water vapor at temperatures between 100 and 350 deg. F. DALTON G. MILLER. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 636-653.—In order to approximate the thickness of the wall in drain tile used in the public ditches in the Middle West, 2 by 4-in. cylinders were used in this investigation. Although small, the cylinders were essentially concrete, and not mortar. No aggregate exceeded ⅜ in. in size. The mix was 1:3, and the water-cement ratio varied from 0.59 to 0.64. After curing with steam, some specimens were exposed to alkaline waters of Medicine Lake, S. D. Ultimate compressive strengths were obtained at 7 and 28 days, and 1, 3, and 5 years. The cylinders cured continuously in water averaged from 0.5 to 1.3 per cent less absorption than cylinders cured in water vapor. For identical curing periods, the absorption was nearly constant regardless of temperature. Concrete cured in water vapor between 100 and 285 deg. F. and stored in water continues to increase in strength at a rate not greatly different from control cylinders cured in water. Photomicrographs show that steam curing produces more complete hydration. No strength is gained by curing in steam at temperatures above 155 deg. F., or by curing more than 48 hours. Resistance to sulfate waters is definitely increased by curing temperatures from 212 to 285 deg. F., and for periods up to 6 days.—GLENN MURPHY

Deterioration of concrete in hydraulic structures. A. EKWALL. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Inspections 10 years ago of hydraulic structures in Sweden displayed some defects in the concrete. Continued observations proved, that concrete in some cases was subject to an increasing deterioration, apparently due to qualities of concrete materials, to methods of making concrete or to conditions to which concrete was exposed. Investigations were arranged with the aim to ascertaining causes of such increasing deterioration. It had been observed that deterioration occurred only in structures exposed to water on one side and was caused by the solubility of lime and decomposition of other chemical combinations in hydrated cement. Particular attention was therefore placed on solubility of cement and aggressiveness of the water. In combination with investigation relating to these factors, practical experiments have been made with concrete slabs exposed to low water pressure during several years. It was proved that Swedish natural waters need not be considered aggressive in this respect. The importance of using sand, relatively free from organic substances, was impressively established. Leaner mixtures than 1:4½ should not be used for concrete exposed to water pressure from one side. Replacing cement by an admixture of 10 per cent lime or 5 per cent calcium chloride improved the watertightness, while 25 per cent trass or slate powder practically gave no improvement.—EDITORS N. I. A. T. M.

Resistance of concrete to chemical attack. K. MANDL. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—In Austria the deterioration of concrete due to injurious influences is relatively slight. The most prominent instance is the destruction of a pillar of a new dwelling house in Vienna, which was definitely found to be due to the action of gypsum. It is especially noteworthy that this damage was not due to sulphate-containing

ground-water, but to surface water that had percolated through the slag-containing fundamental layer, from which it dissolved the sulphate, being then compelled to pass through the concrete pillar, because the slag deposit was laid on material impermeable to water. Several cases of deterioration of the sewer system of Vienna by sulphate-containing water are also reported. A statement is made regarding an investigation into the action of nitrites on concrete, the results of which have been in part already published. It is not yet, however, possible to draw conclusions from this work.—EDITORS N. I. A. T. M.

Designing concrete for high strength, low permeability and low shrinkage. W. A. SLATER. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—High strength and low permeability depend primarily upon using the lowest possible water-cement ratio consistent with securing workability of the mix. Designing concrete for a given strength and low permeability reduces to combining water and cement in predetermined proportions with aggregates in such proportions as to give workable mixes and low cost of finished concrete. Most important requisite for low shrinkage appears to be low cement content. However, excessive shrinkage has resulted from the use of trap rock or conglomerate screenings as aggregate in mortar or from the addition of integral waterproofing compounds. Moist curing is an effective measure for promoting high strength, low permeability, and low shrinkage.—EDITORS N. I. A. T. M.

The properties of cement-sawdust mortars, plain, and with various admixtures. S. H. GRAF AND R. H. JOHNSON. *Bull. No. 3*, Engineering Experiment Station, Oregon State College, Sept., 1930.—Investigation covering practicability of using sawdust in portland cement mortar includes effect of incorporating sand and certain other materials into the mixtures. From a consideration of the use for which this material may be employed, the more important properties are compressive and tensile strengths and thermal conductivity. From tests on these points and also on resistance of material to certain corrosive agents, and from noting relationships existing between the foregoing properties and the presence of bark, the water-cement ratio, the specific gravity, and the age of the sawdust, the following conclusions are indicated: (1) Safe strengths may be obtained from cement-sawdust mixtures. If bark-free sawdust is used there is a small but distinct improvement in strength. (2) Addition of sand has but little effect on the strength and is detrimental where light weight and the lowest thermal conductivity are important. (3) Ratio, by volume, of total water to cement is fair index of strength. (4) Addition of 1 per cent by weight of powdered diatomaceous earth is of decided advantage. (5) Resistance to corrosion of cement-sawdust compares favorably with that of ordinary concrete. (6) Sawdust which has been exposed to weather for a comparatively short time may be used without material loss in strength. (7) Cement-sawdust material is a better thermal insulator than ordinary concrete but does not have as high strength. (8) In order to obtain adequate strength in the cement-sawdust material, it is necessary to use such a rich mixture (large cement content) that the cost, in spite of the cheapness of sawdust, will be greater than that of ordinary concrete. (9) Special care must be taken in control of amount of mixing water and in placing and curing cement-sawdust material if sound durable product is to be obtained. (10) In any given case, the desirability of using the sawdust-cement material in preference to ordinary concrete will depend on the value placed on light weight and on low thermal conductivity.—IRA L. COLLIER

ENGINEERING DESIGN

BRIDGES

Design of a reinforced concrete skew arch. BERNARD L. WEINER. *Proc. Am. Soc. C. E.*, Jan., 1931, V. 57, No. 1, p. 3-112.—The paper includes: (a) A stress analysis based upon the Rathbun method; (b) Theory of proportioning sections; (c) Short-cut for computation of crown stresses in a symmetrical skew "rigid frame" with hinged ends. A numerical example is provided in each instance. Complete derivations of formulas are given for several cases. It is assumed that readers have a working knowledge of the design of a right arch by standard methods.—H. J. GILKEY

North Bathurst street bridge, Toronto. W. D. PROCTOR. *Canadian Eng.*, Dec. 30, 1930, V. 59, No. 27, p. 745.—Steel girder bridge with concrete deck and piers has been completed at a cost of $250,000. Piers consist of four columns 5 ft. by 3 ft. under the cap resting on reinforced concrete footings 17 ft. by 51 ft. which in turn are supported by Westinghouse centrifugal spun reinforced concrete piles jetted into a sandy sub-soil. Concrete deck is carried on four rows of plate girders spaced 14½ ft. o. c. Distance between curbs is 46 ft. with two 6-ft. sidewalks outside. Concrete deck is carried on transverse concrete beams resting on tops of girders and cantilevered out to support sidewalks. Tests of concrete during progress of work showed strengths in excess of 2000 lbs. specified for slabs, piers and abutments and in excess of 1500 lbs. specified for footings.—G. M. WILLIAMS

Design of Box Culverts. G. H. HARGREAVES. *Concrete Constr. Eng.* (England), Jan., 1931, V. 26, No. 1, p. 21-34.—First consideration is that of loadings and resulting bending moments at ends and center of members. Distribution of pressure on base is assumed uniform. Other loads considered are point loads due to wheel loads on the top slab, triangular and uniform loads on side slabs and uniform loads on top slab. Maximum corner moments occur when horizontal slabs are subjected to their maximum loads. Calculation of moments at ends of slabs of a box culvert are simplified by use of diagrams. Bending moments are first expressed in terms of a constant F multiplied by a function of the load on the member and width or height of culvert. Diagrams are given for each type of loading mentioned. The values of the constant F for a selected ratio of moment of inertia of top and side slabs are obtained from the diagrams for ratio of height to width used. Moments thus obtained for different types of loading (a diagram is given for each loading) are then correctly combined to obtain maximum moments. Diagrams are given from which the coefficient F can be obtained for: uniform distribution of load on the base slab combined with concentrated loads on the top slab; uniform distributed load on top and bottom slabs; uniform side loads; triangular side loads. Maximum stresses may be determined in usual way neglecting effect of direct thrust. An illustration shows typical arrangement of main steel. Calculations are given for maximum moments in a box culvert of known dimensions and assumed loads.—JOSEPH MARIN

The Ibis bridge at Vesinet (Seine-et-Oise). A. MESNAGER, F. BARTHES, J. VEYRIER. *Genie Civil*, Jan. 17, 1931, V. 98, No. 3, p. 61-65.—A footbridge rebuilt for automobile traffic presented the difficulty of a minimum clearance

above water level of 6.2 ft. in a 29.5-ft. arch span. A rise of 9.8 in. in 14.1 ft. permitted all vehicles to pass. Novel features of the bridge were steel pipes filled with concrete, which constituted the arch. This "integral reinforcement" offers better resistance to transverse expansion of concrete due to longitudinal compression. Tests of concrete surrounded by a shell of steel were made in 1915 by Rabut at the Testing Laboratory of the École des Ponts et Chaussées and by Professor Baes of Brussels, Belgium, reporting at a convention in Vienna in 1928. Messrs. Mesnager and Veyrier patented an adjustable end connection (a screw stopper) eliminating all danger of loss of strength in tubular reinforcement by contraction. At the beginning of 1930 tests made by the Laboratory of the City of Paris on tubular steel specimens filled with concrete, yielded results resembling those of a theoretical homogeneous specimen, whose Young's modulus, elastic limit and compression strength lie half way between those of steel and concrete. An allowable stress of 2845 lb. per sq. in. is admissible over the entire section, when the ratio of steel to gross section is 0.09 and the weight of steel is 1115 lb. per cu. yd. of total volume. In accordance with the steel ratio, the allowable stress used in the design of bridge was 4980 lb. per sq. in. Anchorage of tubular reinforcement is designed with great care. In filling the shells with concrete, pneumatic hammers produced vibration in the mass leaving the hopper. Concrete mix was proportioned as follows: 1.05 cu. yd. gravel (passing mesh with .39 in. diameter opening); .51 cu. yd. river sand; 880-lb. of Supercilor (special) cement and 31.2-gal. of water. (Supercilor cement requires considerably more water than ordinary cement.) The strength varied with the type of mold used for the specimen, being an average of 4550 lb. per sq. in. for screwed molds and only 2700 lb. per sq. in. for nailed molds, due to a defect. The tensile strengths were 597 and 234 lb. per sq. in. respectively for the two types of molds. Bridge was tested on August 12, 1930, with uniformly distributed load of 815 lb. per sq. ft. and a 10-ton roller.—M. A. CORBIN

Testing concrete bridges. C. S. CHETTOE. *Concrete Constr. Eng.* (England), Jan., 1931, V. 26, No. 1, p. 5-8.—Reasons are given why the deflection tests of concrete bridges should not be the same as for steel bridges (namely a deflection limit of 1/1600 of the span length as the maximum deflection). Loading and deflection tests for concrete bridges should be made at least one year after the completion of the bridge for following reasons: (1) Concrete gains strength with time and the working stresses for concrete are generally based on strength at 90 days. (2) Temperature stresses are more important in concrete bridges than in steel bridges. (3) Cracks that would not otherwise appear, may be produced by deflection tests made before 90-day period. (4) Most of shrinkage of concrete occurs during 90-day period. The particular effects produced in different types of bridges are discussed. In beam and slab bridges temperature changes and resulting stress in the steel may be worth consideration, though effect on concrete is negligible. Shrinkage and plastic effects are discussed. Temperature and other factors in frame bridges are in general slightly more pronounced than in slab or beam bridges. In fixed and two-pin arches the dead load and shrinkage stresses alone will produce plastic yield, as those due to live load will only be applied for short periods and those due to temperature will be subject to reversal. Temperature and shrinkage stresses become of greater importance the flatter the arch. Three-pin arches, if pin friction be neglected, are unaffected by temperature and shrinkage, and are only subjected to local effects of plastic yield. It is evident that almost all concrete bridges vary periodically in strength due to temperature changes, and that they are subject to a progressive strengthening due to the gradual increase in the strength of concrete. Secondary effects due to plastic yield in general, relieve concrete of some stress as time goes on. Usually shrinkage will have little influence after three months. In conclusion, concrete bridge should not be subjected to loading and deflection tests at its completion but tests should be made at least one year after the completion.—JOSEPH MARIN

The International contest for the Dreirosen bridge in Basel (Switzerland). LEOPOLD BERGER. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 59-61.—Designs and costs of proposed structures of steel and reinforced concrete for the Dreirosen bridge over river Rhine in Basel are discussed. Designs were asked for bridge with one or three openings, center opening being at least 328 ft. wide. Costs for reinforced concrete bridges are in general only 9 per cent higher than prices of steel structures.—A. E. BEITLICH

A method of arch design. G. P. MANNING. *Concrete Constr. Eng.* (England), Feb., 1931, V. 26, No. 2, p. 129-141.—To estimate dead load and temperature stresses in an arch without a number of approximations, it is well to calculate beforehand the approximate area required at crown section. It is also useful to know saving effected by using richer mix of concrete and, for an open spandrel arch, best ratio of breadth to depth for the ribs. To obtain uniformity of elastic properties under varying stresses, examination of strength of cross sections under combined bending moment and thrust shows that about 1 per cent steel top and bottom is good assumption. For preliminary investigation it is sufficiently close to assume stress $= \frac{thrust}{area} \pm \frac{moment}{modulus}$ for the case where tension occurs. Example is given of parabolic arch of 150-ft. span and 30 ft. rise. Curves given show relation between approximated temperature stresses (including temperature crown drop stresses) and thickness expressed as a ratio of length. These curves are given for different ratios of rise to span length for both the extrados and intrados and for a rise or fall in temperature of 30 deg. F. Stresses calculated from relation expressed above. Calculations show that temperature stresses are almost independent of the arch profile and practically independent of area of reinforcement (since increase in steel increases moment of inertia in same proportion). For selected arch a diagram shows relation between approximate dead load stresses at crown for uniform dead load and thickness at crown expressed as a ratio of the span length. Curves are given for both the extrados and intrados and for different ratios of rise to span. Increasing the reinforcement from 2 to 4 per cent reduces the stresses about 20 per cent. Similiar approximate curves for stresses at crown section are given for stresses due to a spandrel load. Increasing the reinforcement from 2 to 4 per cent decreases the stresses about 20 per cent. Stresses due to live load are obtained by using the influence line to first obtain values of moment and thrust for crown section. Corresponding crown-drop stresses are readily found from diagram similiar to temperature stresses. Increasing reinforcement from 2 to 4 per cent reduces live load stresses about 20 per cent. Examples apply above diagrams to find thickness at crown of filied-spandrel and open-spandrel arches of given span and rise. The section required is determined for different allowable unit stresses and most economical mix of concrete thus determined.—JOSEPH MARIN

BUILDINGS

The Ford factory at Dagenham. *Concrete Constr. Eng.* (England), Jan., 1931, V. 26, No. 1, p. 8-19.—In factory which will eventually be largest motor car factory in Europe, main block of office buildings is to be 200 ft. long by 50 ft. wide. Three main buildings comprise the foundry and machine shop, the manufacturing building and the assembly shop. A reinforced concrete tunnel 8 ft. 6 in. high and 12 ft. 6 in. wide extends for more than 1000 ft. and carries the power, heating, oil, lighting, and water service mains. Ultimately two blast furnaces of a 24-hour nominal capacity of 500 tons will be in operation. There are to be 45 coke ovens capable of carbonizing 800 tons of coal in 24 hours. A 30,000 k. w. turbine running at 3,000 r. p. m. will be installed in new power house. An important unit is the ore yard for storage and handling of the coal, iron ore and limestone. Work done during the past sixteen months

includes: excavation, 500,000 cu. yd.; piles driven, 13,000; steel work erected, 5,500 tons; reinforced concrete laid, 150,000 sq. yd.; length of railway track laid, 3½ miles; bridges constructed, 2; length of roads constructed on embankments, 1½ miles.—JOSEPH MARIN

DAMS

Third power development in Stave-Alouette group. *Contract Record Eng. Rev.*, Nov. 26, 1930, V. 44, No. 48, p. 1471.—Ruskin hydro-electric power plant of the British Columbia Electric Railway Co., consists of concrete lined tunnels, steel framed power house clothed with concrete and concrete dam of overflow type. Tunnels are 24 ft. in diameter through solid rock and lined with concrete. Dam is of the gravity type 400 ft. long on the crest with a total height of 185 ft., surmounted by concrete piers carrying a roadway, with the openings between piers closed by Tainter gates 33 ft. wide and 26 ft. high.—G. M. WILLIAMS

Construction of Ruskin power project. C. E. BLEE. *Canadian Eng.*, Jan. 13, 1931, V. 60, No. 2, p. 13.—British Columbia Power Corporation, Ltd., has recently completed a power development on Stave River near Ruskin, B. C., including concrete diversion dam of overflow, gravity type, straight in plan with a crest length of 195 ft. and height of 195 ft. above lowest foundation point. On spillway crest piers are 40 ft. o. c. carrying a roadway with Taintor gates 33 ft. by 26 ft. installed between piers to regulate discharge. Dam is designed to have resultant pressure fall within middle third with reservoir full with uplift varying from 50 per cent head at upstream face to 25 per cent at plane of drainage system, and zero at the downstream toe. Total concrete in dam is 105,000 cu. yd. Field mix for body of dam was 1 cement, 3.05 sand, 2.69 gravel (3 in. to 6 in.) which gave about 2,000 lb. per sq. in. at 28 days. Concrete weighed 155.6 lb. per cu. ft. Cement requirement was approximately 1 Canadian barrel per cu. yd.—G. M. WILLIAMS

Some new ideas on dams. EDWARD GODFREY. *Struct. Eng.* (England), Jan., 1931, V. 9, No. 1, p. 11-17.—Practically every failure of a dam, whether of masonry, concrete, or earth, can be explained by underpressure and neglect to provide for underpressure in design. Underpressure at present is rarely emphasized. Only possible reduction of underpressure, assuming either the thinnest fissure, saturated sand or saturated earth beneath a dam, is reduction due to escape of water. For a dam founded on solid rock the possibility for entrance of water, and consequently safety of the structure, depends upon perfection of construction. Escape of water below dam is usually prevented by plugging leaks, thus causing water under dam to accumulate its full head. Where a dam fails by underpressure it may be a sliding failure due to lubricated bottom. Erosion of soil may also follow underpressure. Failures of St. Francis dam in California, Gleno dam in Italy, and Lafayette earth dam in California are explained by consideration of underpressure. Various other illustrations of failures are cited as evidence of the points raised.—V. P. JENSEN

Recent advances in buttress-type dams. CALVIN V. DAVIS. *Civil Engineering*, Feb., 1931, V. 1, No. 5, p. 387-391.—As a result of recent advances in structural design, two distinct types of buttress dams have been developed, characterized respectively by massive buttresses and by thin buttresses. Principal characteristics of thin buttress type are use of minimum buttress thicknesses and spacings, and placing of greater dependence on stabilizing effect of water load on deck than in massive buttress type. Very low sliding factors may be obtained making dam suitable for almost any type of foundation. On soft foundations, limiting feature is span of slab footing between buttresses. Better foundation design is obtained by keeping buttresses

relatively close together thus necessitating thin buttress design. Economy may be obtained by use of massive buttress type with good foundations. New design with round-head buttresses has following advantages: (1) Water loads transmitted in direct compression to buttress through massive cylindrical portion. Radial water bearing face, to which all pressures are normal, eliminates bending and diagonal tension in upstream portion. (2) Shape of buttress gives almost ideal distribution of principal stresses and shear throughout dam. (3) All members are massive and solid. Volume of concrete in massive buttress type is about one-third of that in gravity type, in which governing feature is safety against overturning. Reduction in cost of massive buttress type over gravity type is about 50 per cent for dam 300 ft. high. Aside from development of two types mentioned, most noteworthy advances in design and construction have been improved methods of stress analysis and development of system of buttress construction and contraction joints. Modern methods of stress analysis were introduced in this country 20 years ago by Professor Cain and have been recently adapted to design of buttress-type dams. A more thorough knowledge of stress distribution has been directly responsible for development of improved system for placing construction joints in high buttresses. In laying out system of joints for buttress it is desirable to retain monolithic action of buttress as a whole and to place joints so there will be no tendency for relative movement of buttress sections separated by joint.—D. E. LARSON

MISCELLANEOUS

Discs and disc sectors. *Ostr. Bauzeitung* (Austria), Dec. 20, 1930, V. 6, No. 51, p. 819-22.—Mathematical formulas are given which illustrate nature of discs and disc sections and their importance in static calculations of structures. (cf. *Ostr. Bauzeitung* (Austria), 1930, V. 6, No. 20 and 40.)—A. E. BEITLICH

Introduction to calculations of frame structures. *Ostr. Bauzeitung* (Austria), Dec. 27, 1930, V. 6, No. 52, p. 836-42.—Many tables are used to explain fundamental principles of calculations of structural members. Subjects of discussion are: degree of indetermination of structural members, laws of symmetrical loads, deformation of simple frames and deformation under consideration of torsion and bending effects.—A. E. BEITLICH

Harbor enlargements in Boulogne sur mer (France). BOLLE. *Bautechnik* (Germany), Oct. 3, 1930, V. 8, No. 43, p. 658.—Extensive construction program for enlarging existing harbor structures includes breakwater 1.24 miles long, extension of another breakwater about 2300 ft., excavation of harbor entrance and western part of harbor to a depth of 42.7 ft., quay for passenger service which will be 984 ft. wide, construction of railway station and dock 2300 ft. long.—A. E. BEITLICH

Structural tests on models by Begg's method. J. BLAZEK. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—The author considers the relative advantages and disadvantages of various methods of solving problems in statics by tests made on models; in particular the following: (1) The method of exact reproduction on a reduced scale. (2) The method of photoelastic measurement. (3) The Nupubest method. (4) The Continostat method. (5) Begg's method. The author finally reaches the conclusion that Begg's method is most suitable in practice, provided the accessories are well adapted to their purpose.—EDITIONS LA TECHNIQUE DES TRAVAUX

Coefficient $n = \frac{E_s}{E_c}$ and allowable stresses for concrete and steel in reinforced concrete. M. ROS. *Reports*, First International Congress for

Concrete and Reinforced Concrete, Liege, 1930.—Value of n is not fixed by uniform methods in specifications used in different countries but varies from 5 to 20. Value of maximum compression in concrete as calculated differs from value obtained using n. Hence, following points were investigated: Actual properties of portland cement, increased strength of concrete, values of maximum stresses corresponding to change in value of E_c. Influence of change in value of n on stress in concrete was studied—for stress in steel of 14,250 lb. per sq. in. and 1 per cent steel, maximum compression for concrete = 1050 lb. per sq. in. for $n = 5$, and 615 lb. per sq. in. for $n = 20$. Study was next made of actual values of n for: (1) Flexure—Value of n depends upon the loading. Let M_a = the external moment, M_i = internal calculated moment. Assuming Hookes Law and neglecting tension in concrete, maximum compression in concrete $= \frac{2M_a}{x(h-x/3)}$ and the maximum tension in the steel $= \frac{M_a}{J_c(h-x/3)}$, where x = the distance from outer fibre in compression to neutral axis and h = depth of beam. But x is a function of n therefore $x = nf_c\left(\sqrt{1+\frac{2h}{nf_c}}\right)-1$, where f_c = stress in steel. Values of maximum stresses are thus dependent upon value of n. From stress-strain curves of concrete and steel, stresses for a given section of beam for known load and percentage of reinforcement can be obtained. Internal moment can be calculated assuming plane sections remain plane. With above relations actual values of n can be obtained, using stress-strain curves. Choosing arbitrary values of n the values of stresses in steel and concrete can be calculated for given load. These can then be compared with actual corresponding values of stresses. This method was applied to beam of rectangular section with 1½ per cent steel and subjected to flexure. Results are given by curves, one for each concrete considered for beams with concrete of compressive strength of 2,000, 3,250 and 4,300 lb. per sq. in., with corresponding steel of apparent elastic limit of 38,500, 38,500 and 50,000 lb. per sq. in. respectively. For case 1, n varied from 8.3 to 35 corresponding to stresses in concrete from 0 to 2,000. The calculated compressive strength for $n = 10$ is less than, or equal to allowable compression of 930 lb. per sq. in. For values of stresses greater than allowable there is a difference between actual compressive stress and that calculated for $n = 10$, increasing as stresses become greater. Actual stresses in steel are little different from calculated values, using $n = 10$. For concrete of compressive strength = 3,250 lb. per sq. in., n varied from 6.7 to 13.6. Value of n at failure of beam = 7.2. Good agreement was noted between actual and calculated values of stress in concrete using value of $n = 10$. The ultimate strength as calculated using $n = 10$ and compression in concrete = 3,250 lb. per sq. in. agrees well with the actual value. For concrete of compressive strength = 4,300 lb. per sq. in. n varied from 5.8 to 9.5 corresponding to stress in concrete from 0 to 4,300 lb. per sq. in. Value of n at failure = 6.6. Actual values of compression in concrete are a little higher than those calculated for $n = 10$. For tension in steel, actual values are a little smaller than those calculated for $n = 10$. Strength calculated using $n = 10$ and compression in concrete = 4,300 lb., is a little greater than actual value. At failure by flexure $n = 20$. Actual values of tension in steel are less than calculated values for $n = 10$. (2) Axial compression—Values of n were determined for given load by means of stress-strain curves for three cases, strengths of concrete of 2,000, 3,250 and 4,300 lb. per sq. in. with strength of reinforcing steel of proportional limit = 27,100, 27,100 and 38,500 lb. per sq. in. respectively. For strength of concrete of 3,250 and 4,100 value of n varied from 5 to 12. For these two cases the value of $n = 10$ gives close agreement between calculated and actual values of stresses. For 2,000-lb. concrete, n varies from 8 to 18. Following values are proposed for new Swiss specifications for strength of reinforced concrete, discussed by Swiss Society of Engineers and Architects. (1) Coefficient n is to be taken as 10 for compression and flexure. This value of n gives close agreement between the actual and calcu-

lated values of tension in steel and compression in concrete. (2) For $n = 10$ the values of compression in concrete are 10 to 25 per cent greater than obtained for $n = 15$ or 20. Allowable values are thus increased, corresponding to strengths of concrete cubes in simple compression. (3) Allowable shearing stress is between 57 and 71 lb. per sq. in. Quality of concrete is specified. Allowable values of stress in reinforcing steel is 17,000 and 23,000 lb. per sq. in. for steel whose apparent elastic limit is 39,000 and 50,000 lb. per sq. in. respectively. Allowable stresses in steel and concrete for columns and beams are given.—J. MARIN

Calculation methods. "Bemessungsverfahren." B. LOESER. 1930, Wilhelm Ernst and Son, Berlin (Germany), third edition, R. M. 6.50. Reviewed in *Zement* (Germany), Dec. 4, 1920, V. 19, No. 49, p. 1170.—Book prepared for contractor and designer, explains large number of different calculation methods. Special consideration is given to changes of certain dimensions and the effect of such changes on other structural parts.—A. E. BEITLICH

Reinforced concrete construction. Its theory and application. "Der Eisenbetonbau. Seine Theorie und Anwendung." E. MOERSCH. 1929, Konrad Wittwer, Stuttgart (Germany), V. 1, second part, sixth enlarged edition, 541 pp., 614 illustrations, R. M. 27.00. Reviewed in *Zeitschr. Ostr. Ingenieur und Architekten Vereins* (Austria), Dec. 19, 1930, V. 82, No. 51-52, p. 439.—Entire theory of reinforced concrete construction is explained based on newest research developments. Numerous experiments aid in explanation of subject.—A. E. BEITLICH

Increasing of strength of steel skeleton structures with concrete encasements. FRITZ EMPERGER. *Zeitschr. Ostr. Ingenieur und Architekten Vereins* (Austria), Nov. 21, 1930, V. 82, No. 47-48, p. 406-8.—Author discusses results of tests carried out mostly in United States on structural steel encasements. (cf. Morris and Shank, "Gunite and concrete encasement to increase strength of structural steel," 1928, Columbus, O., and reference list, R. Zipprodt, *J. Western Soc. Eng.*, 1929, No. 5.) Great advantages of this type of encasements are illustrated and their economic importance characterized. Number of profiles of steel girders can be reduced. Static calculations of such structures are given. Similar tests are carried out by Prof. Klockner in Prague (Czecho-Slovak Republic).—A. E. BEITLICH

Handbook for reinforced concrete construction. "Handbuch fuer Eisenbetonbau." H. C. EMPERGER. 1930, Wilhelm Ernst and Son, Berlin (Germany), Vol. 1, fourth edition. Reviewed in *Zement* (Germany), Dec. 4, 1930, V. 19, No. 49, p. 1170.—The new edition of Vol. 1 deals with historical development, experiments and theory. Prof. Foerster wrote first chapter. Experiments carried out by Otto Graf are described and widely discussed. Chapters on statics are treated by Prof. Domke. Results of and experiments with different methods are illustrated and relations between theory and practice are described. Numerous references are included.—A. E. BEITLICH

A practical venturi meter for irrigation service. J. E. CHRISTIANSEN AND I. H. TEILMAN. *Eng. News Record*, Jan. 29, 1931, V. 106, No. 5, p. 187-188. A Venturi meter made of precast concrete tube has been developed to eliminate difficulties common to usual devices used to measure irrigation water. About 50 of these meters ranging in size from 16 to 42 in. were placed in service in the Consolidated Irrigation District near Fresno, Calif., during 1929-1930 irrigating season and were found to be practical for actual field use. Meters consist of three sections of precast concrete pipe to form the tube and a vertical well for measuring heads. Beginning at the upstream end, parts of meter consist of: (1) a short entrance section of uniform diameter containing the entrance pressure connections; (2) combined entrance cone and throat sections with piezometer ring, and (3) exit cone of gradual taper providing a

return to original diameter. Sections are cast in heavy sheet metal forms and reinforced with ¼-in. bars. Installation of tube is similar to manner of installing same amount of concrete pipe.—D. E. LARSON

Structural design and construction of concrete improved in 1930. *Concrete*, Feb., 1931, V. 38, No. 2, p. 16-18.—Conviction that high quality in concrete means density as well as strength has spread in past year. Interest is manifested in use of large size aggregates in massive work, particularly dams, mixers using up to 9-in. sizes. Concrete containing large sizes was tamped or puddled by means of electric-driven tampers or vibrators. Most important development in waterproofing is investigation at Bureau of Standards, of 75 commercial products. Railway engineering association developed formulas for design of flat-slab structures under concentrated loadings. Reinforced concrete frames are being built to greater heights, column sizes being reduced by use of cores of structural steel H-beams or cast iron centers. Light-weight aggregates reduce weight of structural frame and floor. Value of continuous belt conveyor on large project demonstrated in construction of dam near Wilmington, Del. Concrete was successfully transported a distance of 1900 ft. from mixer to deposit. Use of and development of equipment for handling of bulk cement is advancing. Revised specifications for placing of terrazzo floors under preparation by terrazzo association. Use of metal forms in building construction evident.—C. BACHMANN

The Nag Hamadi barrage. *Engineering* (England), Jan. 2, 1931, V. 131, No. 3390, p. 20.—The Nag Hamadi barrage, below Luxor in Egypt, the latest of a series of works built across the Nile to increase facilities for irrigation in Upper Egypt, consists of two abutments, nine main piers each 13 ft. 1 in. wide and 90 intermediate piers, 6 ft. 6 in. wide, supported on a concrete foundation approximately 10 ft. thick, of 1:6 portland cement concrete paved with gravel at the sluice openings. Piers are of limestone ashlar with rubble core, the lower portions being faced with dressed granite.—G. M. WILLIAMS

Statics. Part 1. Fundamental principles of statics of rigid body. "Statik. Teil 1. Die Grundlagen der Statik starrer Koerper." FERDINAND SCHLEICHER. 1930, Walter de Gruyter and Comp. Berlin and Leipzig (Germany), 143 p., 47 illustrations, R. M. 1.80. Reviewed in *Zeitschr. Ostr. Ingenieur und Architekten Vereins* (Austria), Nov. 21, 1930, V. 82, No. 47-48, p. 412.—Chapters of book deal with: introduction, forces with one point of attack, graphic demonstration of forces in the plane, force couple and moment, principle of virtual energy and equilibrium conditions. Extensive reference list is given.—A. E. BEITLICH

Statics of structural members. "Statik der Tragwerke." WALTER KAUFMANN. 1930, Julius Springer, Berlin (Germany), second enlarged edition 322 p., 368 illustrations, R. M. 19.50. Reviewed in *Zeitschr. Ostr. Ingenieur und Architekten Vereins* (Austria), Dec. 5, 1930, V. 82, No. 49-50, p. 424.—Six chapters of book deal with (1) general fundamental principles; (2) moments, transverse and normal forces in statically determinate structures; (3) determination of tensions in statically determinate structures; (4) elastic deformations; (5) theory of statically indeterminate systems and (6) statically indeterminate structures. Book is a comprehensive treatise of this subject. Method of S. Mueller for solution of general elasticity equations with only one unknown is described.—A. E. BEITLICH

New quays in the harbor of Hamburg (Germany). *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 39-40.—New quay wall for Rhenania-Ossag Oil Co., in Hamburg was built during winter 1929-30. Reinforced concrete foundation piles are from 39.7 to 45.9 ft. long and 13.4 in. square. Steel sheet pilings of Larrsen type No. 3, which are 38.7 ft. long, were used. Top of wall is faced with granite slabs. Concrete piles are provided with acid repellent coating. Tracks of travelling crane are supported by wall.—A. E. BEITLICH

Stresses and strains in spirally reinforced columns. F. E. RICHART. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930. In studies of concrete subjected to compression in three directions, it was found that the material in a spirally reinforced column obeyed the same laws as a plain concrete cylinder loaded at the ends and subjected to lateral pressure. Determination of pressure exerted by spirals upon the concrete core required accurate knowledge of stress-strain properties of the steel, together with a comprehensive series of strain measurements on the columns. The plastic condition of the concrete of the column core at high loads was well shown by the flow of concrete past the spiral reinforcement and by properties of the concrete alone after it had undergone large deformations.—EDITORS N. I. A. T. M.

ARCHITECTURAL DESIGN

Church construction "Evangelischer Kirchenbau." 1930, Editor: Beratungstelle fuer kirchliche Kunst beim evangelischen Presseverband fuer Rheinland in Essen (Germany). Reviewed in *Zement* (Germany), Dec. 11, 1930, V. 19, No. 50, p. 1192.—Uses of reinforced concrete and steel in modern church construction are illustrated in comprehensive manner and several examples are given. Development of modern church type in Europe is discussed from viewpoint of the architect.—A. E. BEITLICH

St. Nikolai, a church of reinforced concrete and glass. PAUL GIRKON. *Zement* (Germany), Jan. 1, 1931, V. 20, No. 1, p. 1-24.—Principles of construction and architectural design of an outstanding example of modern church are entirely new. Only glass and reinforced concrete were used. Calculation of frames of east room against wind pressure was very difficult. This room is formed by three glass walls, structural members of which are made of reinforced concrete. Only two 12 by 12-in. columns are erected in corners. Tower structure is entirely separated from main building. It is 167.3 ft. high and has box-shaped cross-section, 21.7 ft. wide, walls being 7.9 in. thick. Horizontal girders (31.5 by 7.9 in.) are arranged 29.5 ft. o. c. They separate tower walls into single reinforced concrete panels 21.7 by 29.5 ft. Foundation of tower consists of reinforced concrete ring 6.6 ft. wide and 27.6 in. thick; it is placed 21.3 ft. deep. Greatest part of article is devoted to consideration of architectural design and characterizes suitability of reinforced concrete for such construction purposes, with detailed description of different parts of interior. Arrangements of lights show entirely new features.—A. E. BEITLICH

FIELD CONSTRUCTION

BRIDGES

Three cableways and precast units speed winter bridge construction. B. A. WILDER. *Eng. News Record*, Jan. 8, 1931, V. 105, No. 2, p. 64-65. —Winter Construction on a $300,000 concrete arch road bridge across Androscoggin River in Maine was made more certain by pre-casting the 250 curtain walls. They were placed by means of cableways—a separate one for each of the three arch ribs.—GLENN MURPHY

BUILDINGS

Concrete structural frame climbs three stories per week. CEDRIC WILLSON. *Concrete*, Feb., 1931, V. 38, No. 2, p. 41-42.—Schedule on 15-story concrete frame, Oklahoma building, calling for 3 floors per week, was easily maintained. By getting high early strength from standard portland cement, contractor was able to use two shifts, and maintain time schedule without

trouble or extra expense. All concrete mixtures were designed by strength charts. Three classes of concrete were used, containing 6, 7, and 8 gal. water per sack of cement. Mixes were designed to contain 6½, 5½, and 4¾ sacks of cement per cu. yd. of concrete. Four sets of forms were used, being stripped in 48 and 72 hr. and 7 days. Test cylinders broken at 3, 7, and 28 days showed high strengths.—C. BACHMANN

New system of construction. *Conc. Building Conc. Products* (England), Dec., 1930, V. 5, No. 12, p. 153.—Hollow precast units are used in the system described, for walls, columns, beams and floors, etc., and it is claimed that the system is adapted for rapid construction, architectural treatment without extra cost, and prevention of condensation. It is cheaper than steel or reinforced concrete. For walls units are standardized in sizes for various thicknesses, with grooves at each end for grouting, and vertical cavities. Face is 2 in. thick granite concrete and the rest is clinker concrete. For columns the vertical cavities are reinforced with steel and concrete and these stanchions may be part of the wall or stand out from face. Beams are formed in precast units used as shuttering, and which form a trough into which concrete and steel may be placed. These units may be granite faced for use as external beams. At junctions with columns, holes are made in beam shells to allow the column steel to pass through. Floor slabs are made in 2 ft. by 18 in. by 8½ in. units with two longitudinal cavities. The sides of slab and webs between cavities are 1 in. thick. Steel and concrete may be placed between adjacent slabs thus allowing beams to be formed within the floor construction. A wide range of cast stone units may be used in conjunction with the system for decorative purposes. These are cast in strong wooden frames divided with metal dividers. Wing nuts and bolts through gas barrel are employed to hold the whole rigidly together. Each mould makes 14 blocks and they are erected in tiers, five high. Concrete mixers are fed by materials from overhead bins, charged by elevators from stock piles outside the building.—JOHN E. ADAMS

DAMS

The Don Martin project. ANDREW WEISS. *Proc. Am. Soc. C. E.*, Dec., 1930, V. 56 No. 10, p. 2141-2160.—Don Martin Project, one of the largest constructed under the Mexican Federal Irrigation Law of 1926, is located on the Salado River in the states of Coahuila and Nuevo Leon. The reservoir covers 48,412 acres, will store 1,123,600 acre ft. and will serve 160,000 irrigable acres. The dam (41 miles upstream from Rodriguez) is a composite concrete and earth structure. The overflow (concrete) section is 768 ft. long, is of the round-head buttress type and about 86 ft. high to spillway crest. The aggregate was crushed limestone from the right abutment. Part of the same material was returned through cone crushers to supply the sand. The concrete plant consisted of two 1 cu. yd. mixers located directly below the storage bins. Concrete was conveyed in side-dump cars. The 3231 linear ft. of earth and gravel embankment section was protected by a concrete slab varying from 11 in. at base to 8 in. at crown reinforced with ¾ in. round bars 12 in. o. c. each way.—H. J. GILKEY

Toro Rapids dam. *Contract Record Eng. Rev.*, Dec. 10, 1930, V. 44, No. 5, p. 1517.—The Shawinigan Water and Power Co. has completed an impounding and regulating dam on the Mattawin River in Northern Quebec located 80 miles from a railway. The dam consists of a bulkhead section of gravity type, a sluiceway section and a control gate section. The Toro dam is 90 ft. high, 2400 ft. long at the crest, including 1700 ft. of earthfill and contains 52,000 cu. yd. concrete. Concrete aggregates consisted of sand excavated from below water level and stone quarried and crushed near the dam site. An inundator was used in proportioning and concrete was distributed by means of a tower and cableway.—G. M. WILLIAMS

Foundation procedure at Owyhee Dam. *Eng. News Record*, Jan. 29, 1931, V. 106, No. 5, p. 178-182.—Foundation problems, complicated by the necessity of excavating and concreting a fault zone 190 ft. below streambed, have been solved at the 530-ft. arched-gravity dam being built for the Owyhee project in eastern Oregon, and concrete placing in the main structure is well started. It was necessary to remove 38,000 cu. yd. of material from 250-ft. length of fault zone. This was followed by replacement with concrete. Completion of this work permitted concreting operations on a full scale, and about 1,000 cu. yd. per shift are being placed in the structure from an 8-cu. yd. bucket handled from an overhead cableway. The mix is proportioned to secure finished concrete having economic balance between qualities of strength, impermeability and durability, with due regard for desirability of using all the coarse aggregate brought to the site. Result of this balancing of concrete characteristics is use of 1 bbl. of cement per cu. yd. of concrete in dam. Strength of concrete averages about 3,500 lb. at 28 days, approximately six times maximum stress of 600 lb. used in design and more than double specification requirements of 1,500 lb. Consideration of factors of impermeability and permanence account for maintenance of this cement proportion. Concrete placed within 3 or 4 ft. of the upstream face is enriched by increasing the cement content to 1.25 bbl. per cu. yd.—D. E. LARSON

The Osage hydro-electric project. G. R. STRANDBERG. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 243-248.—Recently completed project will serve as peak-load plant, serving St. Louis by being tied into the Keokuk hydro-plant and steam plants within St. Louis. Bagnell Dam, located 75 miles above confluence of Osage and Missouri rivers about half way between St. Louis and Kansas City, creates only large lake in Missouri and fourth largest artificial lake in United States, the length being 130 miles, capacity 1,200,000 acre feet (with a 30-ft. drawdown), area 95 square miles (61,000 acres), with drainage area above the dam 14,000 square miles. Average river flow is 10,500 c. f. s. fluctuating between 110,000 and 324 c. f. s. Bagnell Dam is of concrete gravity type 2543 ft. long and 148 ft. from bedrock to floor of 20 ft. wide bridge over dam. The water level can be raised about 105 ft. and a full year's flow can be equalized. Foundation rocks are dolomite and sandstone which lie 25 ft. or more below water section. Bottom widths are from 93 to 107 ft. The dam contains about 550,000 cu. yd. of concrete and 875,000 cu. yd. of earth and gravel were excavated. Capacity is initially 180,000 h. p. (6 units) with 2 service units and 2 additional main units of same type. The plant consisted of a 4-mile construction railway from Bagnell and 2 cubic-yard mixers located just downstream from construction bridge. Sand and gravel for concrete were dredged from river bed 3½ miles down stream from dam.—H. J. GILKEY

Construction of Ruskin power project. (See ENGINEERING DESIGN—DAMS.)

MISCELLANEOUS

When to use piling. A. C. EVERHAM. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 304-6.—The usual considerations controlling the use of piles are reviewed and comparisons made between concrete and wooden piles and between straight sided and tapered piles. Soil tests are mentioned and the reader is warned against drawing sweeping conclusions from small-area tests. For foundations under water, pre-cast piles 115 ft. long and 24 x 24 in. in cross-section were driven for a bridge at Newport News. These are longest piles ever driven and special precautions and methods were required to prevent deflection cracks and to secure proper alignment.—H. J. GILKEY

Glass and reinforced concrete (Glaseisenbeton) and its application for large concrete structures. H. CRAEMER. *Zement* (Germany), Dec. 11,

1930, V. 19, No. 50, p. 1185-8.—A new combination of reinforced concrete and glass, called "Rotalith," is described. New construction method used round glass bodies which are placed into forms and imbedded in concrete. Sides of glass bodies are grooved to secure firm contact between the two materials. Properties of glass as a building material are described. Compressive and tensile strength are very high, modulus of elasticity is also great; due to internal tensions glass is very brittle. A number of vault constructions are described and experiences mentioned. Fire tests showed that glass and reinforced concrete act as a uniform body and have high fire resistance.—A. E. BEITLICH

Construction plant on the Beauharnois canal job. *Contract Record Eng. Rev.*, Nov. 5, 1930, V. 44, No. 45, p. 1384.—In construction of Beauharnois Power Development in Quebec concrete at the power house site is being mixed in 2 two-yd. mixers with all ingredients proportioned by weight. Aggregate is supplied by primary and secondary rock crushers having capacities respectively of 250 and 75 tons per hr. and a sand machine of 65 tons per hr. Four traveling cranes are employed in pouring concrete.—G. M. WILLIAMS

Shaking and stirring of concrete. *Zement* (Germany), Dec. 25, 1930, V. 19, No. 52, p. 1238-41.—In discussion of a paper by Trèves and addresses delivered by Freyssinet and Séailles on importance of shaking and stirring of concrete in molds, two methods are described: (1) Vibrators act on outside of forms and cause packing of concrete mixture. Apparatus designed by Bérenguier, which is called "Vibropyl," is very efficient. (2) Pervibrators are always placed in interior of concrete mass and transmit their vibrations directly. Great advantages of both methods are described in detail. Uniformity of concrete and its compressive and tensile strength are considerably increased. Difficulties, which were encountered in practice and remedies for such cases are illustrated.—A. E. BEITLICH

Encasing wood stave pipe with reinforced concrete. *Contract Record Eng. Rev.*, Nov. 19, 1930, V. 44, No. 47, p. 1435.—To permit landscape improvement of a park through which runs a 13 ft. 6 in. wood stave pipe line of the Hydro Electric Power Commission of Ontario the wood pipe has been encased in reinforced concrete shell which will permit removal of the wood-stave material at some later date. Reinforcing consists of an inner and outer ring of circumferential bars designed to take all stresses due to water pressure. Longitudinal reinforcement is designed to care for maximum temperature changes to which the pipe may be subjected. To fully support the pipe during construction the invert was poured in short saddle lengths of 6 ft. 4 in., carrying the covering up the sides to 60 deg. above bottom center line of pipe. Construction joints were made watertight with keys coated with emulsified asphalt. Concrete (16,200 cu. yds.) was delivered by transit mixers and discharged into chutes leading to bell mouths from which it was directed into place by tubes.—G. M. WILLIAMS

Concrete construction control and practice in the United States of America. H. GRIESEL. *Zement* (Germany), Dec. 4, 1930, V. 19, No. 49, p. 1163-7.—Factors which influence strength and general properties of concrete are: (1) Physical properties, shape, surface and purity of sand. (2) Natural composition of aggregates, petrographic character and influence of gradation on compressive and tensile strength. (3) Necessary amount of water in mixture and consistency. (4) Mixing and transportation, effect of temperatures and weather. Construction of bridge over Hudson River between New York City and Fort Lee N. J. is described as an example of construction control in United States. Results of laboratory tests given illustrate relations between concrete strength and w/c, influence of gradation on strength and most economic mixture which gives desired plasticity and guarantees necessary compressive strength. Tables and curves show sieve analysis and compressive strengths obtained under different conditions.—A. E. BEITLICH

Construction methods—Bridge River tunnel. *Contract Record Eng. Rev.*, Nov. 12, 1930, V. 44, No. 46, p. 1425.—Power project of British Columbia Electric Railway Co. involves boring a 2½ mile tunnel through Mission Mountains. Completed tunnel is horse shoe shape equivalent to 14 ft. 3 in. circular section. Lining requires approximately 34,000 cu. yd. concrete. In pouring the lining the invert or lower portion of the horse shoe section is poured and shaped by template together with short standing walls at each side. On this concrete floor a track is placed to carry a "jumbo" car equipped with a concrete gun and hinged collapsible steel forms, which rest on the base section and after being toggled into position support themselves as well as the weight of the concrete after placing. A pipe equal in length to the section being poured is inserted between form and rock at its highest point, is attached to concrete gun equipment and as car moves backward and forward concrete is forced through and allowed to flow down laterally into position. Concrete is compacted by means of small air hammers striking the outer form surface.—G. M. WILLIAMS

New construction of a quay in Bordeaux—Bassens (France). EMIL STRASSBERG. *Bautechnik* (Germany), Sept. 26, 1930, V. 8, No. 42, p. 643-6.—Reinforced concrete quay, about 8200 ft. long, to replace old structure on wooden foundations, consists of reinforced concrete piers connected by reinforced concrete arches. Piers are about 15 ft. high, 18 ft. wide and each rests on 31 octagonal reinforced concrete piles 15.7 in. in diameter and 62 ft. long. Part of piles have inclination of 1:4, 1:8, or 1:10. Each one carries load of 27.5 tons. Piers are 22.6 ft. deep and reinforced with steel rails. Arches have span of 27.9 ft.; they are 33.5 in. thick at centers and 55.1 in. near piers. Longitudinal reinforcements are placed in lower part of arches and in top part above piers. There is no connection between them. Piers are partly protected by granite facings. Mixture consisted of 772 lb. cement, 14.2 cu. ft. fine gravel and 28.2 cu. ft. of coarse gravel and had a plastic consistency. Detailed description of arrangement of site of construction and piling work is given.—A. E. BEITLICH

Vibro system of concrete piles. *Contract Record Eng. Rev.*, Oct. 29, 1930, V. 44, No. 44, p. 1362.—Vibro system of concrete piling involves driving into the ground a plain steel tube with a cast iron conical shoe, placing reinforcement in the tube if desired, and filling the tube with concrete after which the tube is removed. Operations of driving and with-drawing tube are performed by same steam hammer which requires use of a comparatively light supporting frame. The supporting frames are built in sections and used in heights of 50 and 64 ft. for making piles 34 ft. and 45 ft. long. Cast shoe is placed in position on ground surface and hollow cylindrical shell or tube set in position and fitted to shoe to make a water-tight joint, after which it is driven to proper bearing. Hammer blow is transmitted to tube through a metal covered wooden driving cap which fits into a cast steel helmet which in turn is welded on to a steel casting which rests on the top of tube. If reinforcement is used, the hammer and helmet are raised and the fabricated metal lowered into position. Concrete is placed through an opening in the side of the steel helmet at such a rate that the cavity below ground level is full when the tube has been withdrawn 1/3 the distance. In withdrawing the tube after each upward stroke of the hammer the tube is permitted to descend about one half the distance which it is raised, thereby ramming and compacting the concrete and thoroughly filling the space occupied by the walls of the tube. This vibration tamping action results in the formation of corrugations on the pile surface which are claimed to increase bearing power. A two-ton, single acting steam hammer is used. In average ground the bearing power of 32 ft. Vibro pile is said to be about 150 tons.—G. M. WILLIAMS

Construction of Lacroze subway railroad system in Buenos Aires (Argentina). ALOIS POLLAK. *Zeitschr. Ostr. Ingenieur und Architekten*

Vereins (Austria), Nov. 21, 1930, V. 82, No. 47-48, p. 401-3.—Second subway line, built by Ferrocarril Terminal Central de Buenos Aires, connects north western part of city with center and serves as freight line during night hours. Total length of this 15 million dollar project is 22,000 ft., 12,400 ft. of which was built in open excavation. Tunnel, 1394 ft. long was constructed underneath Maldonado river. Latter was provided with reinforced concrete floor. Reinforced concrete predominated in entire construction. Total of 157,000 cu. yds. of concrete and 7275 tons of reinforcements were used. Inner width of single tunnel is 13.39 ft. and of twin tunnel 28.54 ft.; tunnel is 19.36 ft. high. Passenger stations are all of similar design, 426.5 ft. long and from 47.6 to 68.9 ft. wide. Ventilating shafts are placed every 426.5 ft.—A. E. BEITLICH

Chicago open-well method. W. J. NEWMAN. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 306-8.—The Chicago open-well method, devised by General William Sooy Smith about 40 years ago, is well adapted for penetrating blue clay of the Chicago region to hard limestone that lies as deep as 130 ft. below surface. Clay is stiff and can be excavated in 3 to 6 ft. sections and lagged with 2 or 3 in. beveled-edge lagging held by two metal rings on the inside. Excavation is by hand and circular buckets about 2 ft. high and 20 in. in diameter are hoisted with an electrically operated niggerhead winch. Concrete is placed by pouring directly into the well. The top 4 ft. of caisson is usually reinforced with hoops and vertical rods and mixtures commonly used have been 1:2:4 or 1:1:2 depending upon design requirements. The rings and lagging are often removed ahead of concreting. In blue clay the hole is usually dry but the method must be varied when water-bearing seams are encountered. Methods for meeting different aspects of water problem are outlined. Recently rotary excavation machines have been used satisfactorily for caisson work of Chicago type.—H. J. GILKEY

Underground construction. "Grundbau." M. BENZEL, 1930, B. G. Teubner, Leipzig and Berlin (Germany), fifth edition, 238 illustrations, R. M. 4.40. Reviewed in *Zeitschr. Ostr. Ingenieur und Architekten Vereins* (Austria), Dec. 5, 1930, V. 82, No. 49-50, p. 425.—First part deals with investigation of underground by means of test piles and drilling. Then excavating and different methods of pilings are described. Coffer dam and caisson jobs are illustrated. Third part shows protection of excavations against water and frost. Descriptions of modern tools and machinery are given in detail.—A. E. BEITLICH

Use of caissons in St. Louis sub-soil. S. W. BOWEN. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 309-311.—St. Louis bedrock consists of limestone at a usual depth of 50 to 80 ft. Open concrete caisson construction is quite successful in foundation work. A common outside diameter is 8 ft. with 9 in. walls although both vary. The shell is reinforced against both outward and inward pressure. Excavation may be accomplished with a dredging bucket, orange-peel bucket or by hand. No metal cutting edge is used except where boulders or other obstructions are found. Various loading devices are used for keeping the caisson properly aligned and outside lubrication with water jets is sometimes required. A moderate amount of shooting may also be employed near the base of the caisson. When quicksand or other water-bearing strata are encountered, pneumatic methods may be used by placing an air lock on top of the shell. After caisson has been properly grounded and rock cleaned the shell is filled with concrete somewhat leaner than that of which the shell is made. Buildings such as the Statler Hotel, Lennox Hotel and Civil Courts Building, are supported on foundations of this type.—H. J. GILKEY

Yearbook of the German Society of Engineering. "Jahrbuch der Deutschen Gesellschaft fur Bauingenieurwesen." S. BAER. 1930, V. D. I.-Verlag, Berlin (Germany), V. 5, 216 pp. R. M. 12.00. Reviewed in *Zeitschr. Ostr. Ingenieur und Architekten Vereins* (Austria), Dec. 19, 1930, V. 82, No. 51-52, p. 438.—Newest developments of construction methods are

described. Special consideration is given to construction of large storage houses, mining and marine structures. A list gives short descriptions of 310 great German and Austrian construction jobs completed in 1928 and 1929.—A. E. BEITLICH

Twelve month construction. JAMES S. TAYLOR. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 322-325.—The analysis includes a consideration of relative costs and other pertinent factors for the several types of construction. The usual technique and suggested precautions of preheating materials and use of salamanders are included for concrete. There is also a warning against fire risks and too rapid application of heat. Conclusion is that 12-month construction has proved its soundness and its right to united support. —H. J. GILKEY

Winter construction. "Mitteilungen ueber das Bauen im Winter." FRITZ EISEMANN. Kalk-Verlag G. m. b. H., Berlin W62 (Germany), R. M. 0.40. Reviewed in *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 64.—It is shown that winter construction can be made successful in many construction jobs by considering only few precautions and with only small extra costs. Small book treats subject from the economic viewpoint.—A. E. BEITLICH

Pre-cast concrete electrolytic tanks. HECTOR FARAH. *Canadian Eng.*, Dec. 9, 1930, V. 59, No. 24, p. 691.—Concrete has supplanted wood in the manufacture of 1216 pre-cast reinforced concrete tanks for the electrolytic refining of blister copper at plant of the Ontario Refining Co. Ltd., Copper Cliff, Ontario. The concrete cells, 11 ft. 3 in. long, 3 ft. 6 in. wide and 3 ft. 9½ in. deep, inside dimensions of precast members with wall thicknesses ranging from 3½ in. to 4½ in. were made of a special concrete mix consisting of 10 bags of cement per cu. yd. with very little sand and crushed rock not over ½". All steel reinforcement is protected by not less than 1 in. of concrete to prevent short circuits. Reinforcement consisted of specially designed mats of ¼-in. wire and spaced with 1-in. concrete blocks. Interior surfaces were protected by a lead lining and the exposed concrete painted with asphalt paint.—G. M. WILLIAMS

Chicago and North Western establishes quality control of concrete. O. F. DALSTROM. *Concrete*, Feb., 1931, V. 38, No. 2, p. 19-22.—In 1928 railroad adopted new specifications using water-cement ratio as basis of design for mixtures, following in general those adopted by American Railway Engineering Association. Results have shown necessity for being thoroughly organized and equipped for testing, inspecting and controlling concrete from time sources of supply are chosen until product is in forms, to insure proper interpretation of specifications and instructions. Because of great difference in new specifications from old, copy of specifications was sent to each contractor before bidding; special set of instructions on design of mix to division engineers, contractors and inspectors to accompany specifications; instructions to inspectors covering methods to be followed in field and requirements regarding water-control equipment on mixer. List of testing equipment and places of purchase was distributed to insure use of correct equipment. All field equipment was found without adequate water control in first year. This condition was completely corrected in 1930. Automatic time control devices are required. Test specimens of every mix are made in pairs, numbered in consecutive order throughout entire job, odd-numbered specimen being for 7-day test and following even-numbered specimen for 28-day test. Copies of test reports are sent to engineer of bridges, division engineer, inspector, and contractor, to guide and to stimulate interest. Samples of aggregates are submitted to railway company laboratory for test and approval. Railway's engineer visits each job occasionally or on request from division engineer or inspector, to settle questions regarding specifications or materials and equipment furnished by contractor.—C. BACHMANN

The manufacture and placing of large masses of concrete. L. BONNET. *Summary Reports*, First International Congress for Concrete and Reinforced Concrete, Liege, 1930.—Special precautions are necessary in mixing large quantities of concrete that have to be carried a great distance before placing in the work, to prevent segregation. Moreover manufacture of concrete in large quantities demands perfected plant both for actual mixing and for proportioning. During extension work in Port of Antwerp interesting observations were made in regard to concrete made from Rhine gravel and sand. Tests showed that best proportions of sand and gravel to use in making large masses of concrete are as follows: (1) 10 parts gravel to 7 sand, when the size of the gravel does not exceed 1.18 in. and when lead is short. (2) 10 parts gravel to 7½ sand, when the size of the gravel does not exceed 1.18 in. but when lead is long. The same proportion can be used if gravel is coarse while lead is short. (3) 10 parts gravel to 8 sand when gravel is coarse and lead is long. The second part of paper describes installation for making concrete in extension works of Port of Antwerp.—EDITIONS LA TECHNIQUE DES TRAVAUX

Handbook for reinforced concrete construction. "Hilfsbuch fur den Eisenbetonbau." VICTOR HIETZGERN AND ARNOLD ILKOW. 1930, Julius Springer, Vienna (Austria), R. M. 5.80. Reviewed in *Zement* (Germany), Dec. 11, 1930, V. 19, No. 50, p. 1192.—Book is treatise of entire field of structural materials and deals with proper preparation and working in reinforced concrete construction. Book is devoted to use by contractor and designer.—A. E. BEITLICH

Economy of distribution towers for cast concrete in superstructure construction. "Die Wirtschaftlichkeit des Gussbeton-Foerderturmes im Hochbau." R. FINNERN. 1930, W. Kohlhammer, Stuttgart (Germany), R. M. 3.00. Reviewed in *Zement* (Germany), Nov. 27, 1930, V. 19, No. 48, p. 1146.—After showing historical development of concreting methods, author describes economical properties of distribution arrangements for cast concrete. Conditions are illustrated under which installation of towers is advisable. Different examples are given and discussed from an economic view point.—A. E. BEITLICH

Twelve-month construction. JAMES S. TAYLOR. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 322-325.—During last decade winter construction has greatly increased as compared with period before the World War. Some of the causes underlying the change are: (1) pre-war experience with winter construction was greatly multiplied by war-time undertakings, (2) twelve-month construction of many types has a sound economic foundation, (3) the problem affects so large a section of the community that it is of importance to many other lines of business as well as to the public generally. The process employed in the winter construction of concrete consists usually of heating the fine and coarse aggregates, heating the mixing water, protecting stock piles, and housing materials affected by moisture, as well as entire mixer and plant. The temperature of concrete when placed should be above 60°. Protecting concrete while placing and curing is more important in building operations than in bulk work such as bridge and dam construction. Relatively smaller section of a beam or column is more readily and seriously affected by freezing than larger mass of bridge abutment or section of dam. Bulk concrete also provides more heat in setting. It can be housed very cheaply because of its compactness. The housing of building construction is more expensive, but it is seldom necessary to house more than story under construction. The heating is usually done with salamanders.—D. E. LARSON

Use of caissons in St. Louis sub-soil. S. W. BOWDEN. *Civil Engineering*, Jan., 1931, V. 1, No. 4, p. 309-311.—In order to meet unusual foundation conditions existing in St. Louis, there has been developed, in recent years, a rein-

forced concrete caisson which can be sunk to rock by open-well method, using air locks only where quicksand and water are encountered in such quantities as to make its use absolutely necessary. These caissons are hollow cylinders whose inside diameter is usually determined by the size of bucket used in excavating. Walls are made of such thickness as to give the proper outside diameter for the load to be supported. An outside diameter of 8 ft. is frequently used with 9-in. walls. For smaller sizes, excavation is by hand or by small orange peel bucket. No metal cutting edges are used except where boulders or other obstructions are apt to be encountered. Reinforcement consists of sufficient metal, both vertical and horizontal, to prevent cracking of walls, and this is placed in both faces. The minimum reinforcement generally used consists of bars $\frac{5}{8}$ in. in diameter, 12 in. from center to center for the hoops, and 24 in. for the verticals. Where it is likely that air will be used, the reinforcement is designed to take the unbalanced internal pressure, using unit stress of 15,000 lb. per sq. in. for the steel.—D. E. LARSON

Construction joints in concrete. NORMAN DAVEY. Dept. of Scientific and Ind. Research Build. Research Station (England), *Special Report No. 16*, 74 p.—The disadvantages of improperly made construction joints are mainly lack of strength and adhesion at the joint, efflorescence at joints, disintegration due to freezing of water in joints, susceptibility to percolation of moisture, disintegration due to penetration of substances in solution and failure under action of heat. Laitance at joint which is detrimental to proper bonding is usually due to excessive mixing water or even excessive ramming causing segregation of aggregate. Scum, dirt, clay, oil or grease should also be removed. Consistency of concrete should be carefully controlled so that mix will flow sluggishly when tamped into position. Method of washing joints with soda has been tested and found to be in no way harmful, provided all trace of soda is removed. Chipping and wire brushing old concrete has given good results but age of old concrete appears to be of considerable importance. Portland cement may be weakened by chipping while concrete is still green (at 24 hrs.), while after concrete has thoroughly hardened there is a falling off of bond strength due to difficulty of chipping and greater differential shrinkage between new and old concrete. Aluminous cement gives lower bond strength at earlier ages owing to greater shrinkage. For rapid hardening cement, chipping or treating the surface with hydrochloric acid and in both cases grouting with neat cement gives 70 per cent efficiency while for aluminous cement, acid treatment gives better efficiency. Results of tests on joints with old concrete prepared with proprietary compounds are given, and in most cases good results are registered. For applying new concrete to prepared surface of old, a sufficiently plastic mix must be employed to allow it to enter all interstices. A slump of 2 in. is recommended as minimum, while too wet mixes should be avoided. Durability of joints appears to increase with age. For two-layer work upper courses should be laid on lower before it has appreciably hardened. It is found that high adhesive strengths with a joint give watertightness. Aluminous cement concrete does not adhere so readily to rapid hardening types of cement as to ordinary portland cement. Joints in foundation rafts and footings should be cast to their full depth in one operation if possible. Any joints formed should be normal to the compressive stresses. Columns should be cast up to point just below the soffit of beams and left to set before beam and top of column are poured together. Beams may be stopped best at middle thirds, joints at points of excessive shear being avoided. Slabs should not have a horizontal joint and are best stopped at middle thirds.—JOHN E. ADAMS

Progress in reinforced concrete super structure construction during the year 1929. WILHELM PETRY. *Report 33rd main meeting German Concrete Association*, March 17, 1930, p. 142-92.—Important changes were made in preparation of sand and gravel for concrete by producing a greater number of gradings and using better proportioned mixtures, which fact resulted in

considerable increase in compressive strength. Many valuable experiences were obtained in winter construction methods during severe cold weather periods of winter 1928-29. Modern construction methods and improved equipment make winter jobs economic. Great progress was made in construction with sliding forms; system Heine was invented and used for erection of two monolithic chimneys (459.4 ft. high with 20 ft. inner diameter at top), built for power station in Schwandorf (Germany) (cf. O. Hoffmann, *Zement* (Germany), Aug. 28, 1930, V. 19, No. 35, p. 828-34) in a period of only 3½ months. About 8.2 ft. per day were concreted. Six silos were built for Wicking cement plant in Neuwied (Germany), which are 65.6 ft. high and 26.3 ft. in diameter; walls are 7.9 in. thick. System Rohmeyer was used for construction of grain silo in Duesseldorf (Germany), which consists of 10 circular cells with diameters of 26.9 ft. Complete winter structures are 4 cement silos with 8800 tons capacity in Blaubeuren (Germany). Work was started in Nov., 1929, concrete was placed daily and work was completed in 5 weeks, with interesting construction details. Torkret method for concrete roofs saves much time and labor. Arrangement of site, transportation of materials and use of newest machinery made construction of office building Sprinkenhof in Hamburg (Germany) a full success. Two towers distributed about 235 cu. yards of concrete (in 10 hr.) daily. A new type of concrete pump was used with great advantage for number of structures (cf. W. Haevernick, *Bauingenieur* (Germany), Feb., 1930, V. 11, No. 7, p. 100-2; *J. Amer. Conc. Inst.*, Sep., 1930, V. 2, No. 1, Abstr. Sect., p. 18; Heidorn, *Bauingenieur* (Germany), May 30, 1930, V. 11, No. 22, p. 381-4). In several office buildings, skeleton structures, engineering efficiency gave excellent results. Of special interest are construction of City Hall in Ruestringen (H. Kuball, *Der Bauingenieur* (Germany), May 16, 1930, V. 11, No. 20, p. 349-52), buildings of Englehardt brewery (Herbst, *Zement* (Germany), Aug., 14, 21, 1930, V. 19, No. 33-34, p. 776-9, 800-4, *J. Amer. Concr. Inst.*, Nov. 1930, V. 2, No. 3, Abstr. Sect. p. 78) and warehouses of Merchants Corporation in Barmen (*Zement* (Germany), Oct. 30, 1930, V. 19, No. 44, p. 1039-41). Industrial structures, built during 1929, include several large factories, storage houses of nitric acid plant and coal house of a mine. Results of tests of Austrian Government concerning use of high quality steel for reinforcements of concrete columns are included.—A. E. BEITLICH

Special carfloat used to distribute bulk cement. (See MATERIALS—CEMENT.)

Structural design and construction of concrete improved in 1930. (See ENGINEERING DESIGN—MISCELLANEOUS.)

ROADS AND PAVEMENTS

Concrete road junctions. R. A. B. SMITH. *Concrete Constr. Eng.* (England), Jan. 1931, V. 26, No. 1, p. 35-41.—In description of construction of concrete road junctions, order in placing concrete for parts of junction is outlined and illustrated for different types of junctions. Diagrams show different methods of placing construction joints. The simple case of one road meeting another at right angles is first considered. For two roads intersecting at right angles six arrangements of joints are given. For three roads meeting in which the roads have different widths a special arrangement for junction is given.—JOSEPH MARIN

Nation constructs 10,200 miles of concrete roads in 1930. *Concrete*, Jan., 1931, V. 38, No. 1, p. 13-14.—With December figures partly estimated, total yardage of concrete pavements, including roads, streets and alleys, should be about 144,000,000 sq. yd. in 1930, or about 3 per cent over 1929. Trend toward greater use of high grade equipment is seen in fact that 32 states

now require machine finishing of concrete pavements, compared with 26 states a year ago. Sixteen states now demand definite 28-day strength, compared with 13 states a year ago. Definite water-cement ratio is specified by 24 states, compared with 17 a year ago; 29 specify a minimum quantity of cement per cu. yd. of concrete. All states now specify a minimum mixing time, ranging from 50 seconds to 1¾ minutes. All except two require attachment of timing device to control time of mixing, and all except one require measurement of mixing water. Cross-sections of concrete highways are now required to have some type of thickened edges in all but seven states.—C. BACHMANN

SHOP MANUFACTURE

Testing of artificial stone, especially concrete block. R. AMMON. *Chem. Techn. Rundschau* (Germany), 1930, V. 45, p. 157-9.—Experiments were made to determine weight per cu. ft., specific gravity, porosity, absorption properties, hardness, durability and resistance to abrasion of several types of artificial stone and concrete block.—A. E. BEITLICH

Recent noteworthy executions in cast stone. *Betonwerk* (Germany), Aug. 30, 1930, V. 18, No. 35, p. 491.—A description of recent noteworthy executions in cast stone includes that of a large monument, several pieces of garden sculpture, tombstones and a small building illustrated. Each item of execution is analyzed in detail, in a manner to indicate the kind of cast stone, how made and finished. The name of designer in each case is indicated.—HERMAN FRAUENFELDER

Profitable manufacture of concrete building units. FRED A. SAGER. *Concrete*, Feb., 1931, V. 38, No. 2, p. 27-31.—In working out uniform production rate and scheduling output, year's business is analyzed. Based on estimates of use, stock for new 2 by 4 by 8-in. brick was arbitrarily set at 30,000 units for first year and included with the five major items of production of previous year. Total stock Jan. 1, was 70,000 equivalent 8-in. units, made up of quantities as determined from table given for five major items and 30,000 brick. Plan is to increase production to 30,000 units per month for most of the year, allowing for severe cold weather. Estimate of future year's business is on data of three or more past years, when records of years considered are shown by curves, continuation of which in next year serves as basis for that year's production. As year progresses, actual deliveries running ahead or behind estimated deliveries will be indicated and program altered accordingly. Items to be produced in any month will be determined by knowledge of business ready for delivery or in immediate prospect. For ready reference, records of manufacture, sales, and stocks are desirable in the form of diagrams or graphs, which can be projected into the future.—C. BACHMANN

Manufacturing and selling problems occupy products industry. *Concrete*, Feb., 1931, V. 38, No. 2, p. 13-15.—Continued use of concrete masonry and back-up units in large buildings, sustained interest in light-weight aggregates, development of use of colors, and growing attention to manufacturing and selling problems are some of outstanding developments in concrete products industry of 1930. Causes of shrinkage cracks in masonry walls are definitely determined. Cracking can be avoided if units are completely cured and air-dry before being used. Research associate at Bureau of Standards will inaugurate research program on cinder concrete building units covering a number of years. Progress has been made in New York with development of light-weight aggregate by sintering ashes and cinders from low-pressure boilers and other sources from which cinders, in raw state, are not suitable as aggregates. Improved design has made light-weight unit possible in some

cases where ordinary aggregate are used. Vibrating equipment is being used, especially in cast stone, concrete pressure pipe and drain tile manufacture. Use of color in cast stone and ordinary products is receiving increased attention and manufacture of concrete burial vaults is in more satisfactory condition. In new construction method, concrete masonry units, laid up as dry masonry, are "welded" by cement gun which shoots mortar into joints and coats surface. New specialty is metal-faced light-weight concrete slab or block for exterior or interior trim using any commercial metal as facing material.—C. BACHMANN

Spun concrete and reinforced concrete pipes., ERWIN MARQUARDT. *Bautechnik* (Germany), Sept. 16, 1930, V. 8, No. 40 p. 587-602.—After discussing historical development author explains fundamental principles of spinning process. Movement of materials in mold and necessary speed of rotation are illustrated by a number of mathematical equations. Some separation of aggregates and cement is always caused by centrifugal force, coarse parts being accumulated in outer portion of wall while lighter parts and cement are forced to interior. Following means for prevention of separation are advised: (1) Mix should not be too wet; plastic concrete has best consistency. (2) Aggregates should have rough surface and compact form, (3) Aggregates should be of as similar petrographic character as possible. Gradings over 0.6 in. should be avoided. (4) Manufacturing of pipes can be carried out in different layers with adjusted speed of rotation. Different manufacturing processes now in practice in United States and Germany are: (1) Dyckerhoff and Widman in Dresden (Germany) make pipes about 50 ft. long with inner diameter from 3.8 to 5 ft. They are reinforced with cylindrical wire cages with one or two spiral windings. Pipes are suitable for pressure lines under low heads. Belljoints connect pipes with small diameter while spun precast collars, reinforced with 2 spirals are used for larger sizes. (2) A high quality pipe for high pressures which is absolutely watertight is a steel sheet pipe covered externally and internally with layers of dense concrete. Spiral windings are wound first on special machine and then tightly placed inside and outside of steel cylinder. Outer coating is made of high early strength cement and placed in standing form while inner layer is spun after mounting steel form on driving wheels. Mixtures range from 1:3½ to 1:4. After spinning is completed (about 20 min.) excess water which is squeezed out is removed. Pipes are taken out of forms after 24 hours and stored in yard being kept wet by sprinkling for several days. Transportation, placing and jointing are described. (3) Hume process widely used in Europe and United States, is divided into 2 distinct periods. Forms are rotated first at slow rate of speed (200 to 300 r. p. m.) which forms a dense layer of uniform thickness in wall of pipe. Excess water is drained and interior surface is smoothened with a round steel rod during second spinning period (550 to 700 r. p. m.). Forms and pipes are carried to steam kilns and cured from 8 to 12 hr. with low temperature steam. Further storage is in yard. Joints are made with collars and hemp packings. Inside joints and one outside joint between collar and pipe are made in field. (3) Pipes of Vianini type are usually made in France. Molds do not rotate on wheels but are fastened between 2 side discs which movement is claimed to be free from vibrations. Different types of joints are illustrated. (5) Lock Joint Pipe Co., Ampere, N. J., manufactures pipe from 1.3 to 9 ft. in diameter for high heads. Longitudinal reinforcing rods are tied to wire cages by hand or by welding. Ingenious design of joints makes placing and jointing very easy. (6) Main feature of system by Moir and Buchanan is special feeder which at the same time secures uniformity of wall thickness. Pipes are of very dense structure. (7) Short description is given of several asphalt coated pipes. Last part discusses properties of spun concrete pipes such as strength, static tensions, water impermeability, resistance against mechanical abrasion and chemical influences, hydraulic capacities and economy. —A. E. BEITLICH

Materials

Aggregates

Concrete from Slag. J. Bentkowsky. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—The report deals with a series of tests carried out by the Institute of Metals in Leningrad with a view to studying possibility of using a given slag for manufacture of concrete, and determining the mix from these tests in relation to workability and strength.—Editors N. I. A. T. M.

Influence of split on strength of cast concrete. Luz David. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 32-7.—Field tests were made to study improving effect of additions of split to concrete on its compressive strength. One high-grade quartzite split and a low-grade quartz porphyry split were used in 1:1:5 and 1:2:4 (cement-split-sand) mixtures. It was found that compressive strength is considerably increased by even small additions (1/5 of sand) of split. This increase is greater when high early strength cement is used. In this latter case, low-grade split seems to give greatest increases in strength. Question whether such additions are economic in practice or not is discussed and ideal conditions described. Price of split and facilities at site of construction are chief governing factors.—A. E. Beitlich

Plant design and practices—Part 1. G. W. Maisak. *Rock Products*, Feb. 28, 1931, V. 34, No. 5, p. 71.—The first problem considered is that of a feed hopper to a primary crusher, in this case a jaw crusher. A common form uses old rails for lining. These should never be set at an angle greater than 40 deg. to minimize damage from surges of rock. This type of hopper is affected by weather conditions and the amount of dirt coming from quarry. Stone-on-stone type of feed box is favored, as once built it needs no further attention. In the larger plants it should be made of fabricated steel.—Edmund Shaw

Barges bring aggregate to ready-mixed concrete plant at Tacoma. Chas. F. A. Mann. *Pit and Quarry*, March 11, 1931, V. 21, No. 12, p. 56-58.—At new concrete plant of George Scofield Co., which produces Tru-Mix concrete, aggregates are received on barges, chiefly from pits belonging to an interlocking company. Barges are unloaded by hammerhead crane built in company's shops and which rests on a steel framework above piling. The 65-ft. boom carries a 2½-cu. yd. clamshell bucket, and handles 65 cu. yd. per hour into a 10-cu. yd. steel hopper. Material drops to belt conveyor which delivers to conveyor on upward slope of 15 deg. to the storage house. Material can be deposited on bunker-storage belt or carried to bunkers above mixing platform. Bunker-storage belt delivers to the bins. Beneath the storage a conveyor will reclaim the material and beneath the bunkers of the mixing plant the steel chutes have cut-off gates to the scale pan above the mixer. Pan has steel chute to 2-cu. yd. mixer beneath. Cement now measured in a small steel dump-cart will be handled same way as aggregates. A mixometer provides an accurate check on concrete inside the mixer. Concrete is delivered by trucks.—A. J. Hoskin

Aerial photography in the aggregates industry. Howard Maxwell. *Rock Products*, Feb. 28, 1931, V. 34, No. 5, p. 41.—It is often imperative to have maps of aggregate operations, construction projects and sites for either of these. Aerial photographs make best maps, being absolutely accurate and showing details that could not be shown in maps without excessive cost. Now even amateurs who thoroughly understand photography may make aerial photographs that will serve ordinary purposes. Comparatively small areas can be covered with one or two exposures. An exposure made at 7,200 ft. with

a camera of ordinary size will give an accurate map of approximately 200 acres at a scale of 1 in. to 600 ft. This can be enlarged to any scale up to 1 in. to 200 ft. Wide angle lenses are not recommended as they are liable to produce distortion and are usually slower than other lenses.—EDMUND SHAW

Fifth annual report of the engineering and research division. STANTON WALKER. *Nat. Sand Gravel Bul.*, Feb., 1931, V. 12, No. 2, p. 29-37.—Brief summary of work under way in laboratory of National Sand and Gravel Association includes: (1) Effect of characteristics other than grading on concrete-making properties of concrete aggregates—includes studies of mineral composition, surface texture, strength, shape and miscellaneous physical properties of coarse aggregate particles. (2) Effect of size and grading of aggregate on quality of concrete—deals principally with coarse aggregates, although preliminary studies of fine aggregates have been made. (3) Method of proportioning concrete—the development of a logical and scientific basis of proportioning concrete is essential to studies of aggregates for concrete, and is particularly pertinent to the investigations mentioned above. (4) Tests of sand—studies to date have been of a preliminary and exploratory nature, but they indicate the need for a comprehensive investigation. (5) Characteristics of gravel ballast—studies of physical properties and service records of gravel ballast and preliminary work in a study of methods for testing stability of ballast of different types and gradings. The principal efforts of the laboratory for the coming year will be directed to the study of the following problems: Effect of coarse aggregate characteristics other than grading on strength of concrete; methods of tests for durability of aggregates and concrete; correlation of tests of sands with their concrete-making properties; and studies of size and grading of aggregates with particular reference to methods for proportioning fine and coarse sizes for concrete.—P. MCKIM

Produces aggregates and central-mixed concrete for Philadelphia area. *Pit and Quarry*, Feb. 25, 1931, V. 21, No. 11, p. 27-31.—Aggregates used by Liberty Corp., are dredged from the Delaware River and transported in barges to dock at plant. Material averages 60 per cent sand, 40 per cent gravel. Dredge is of steel construction and of the bucket-ladder type. Products of four grades are chuted to barges. At the unloading dock materials are handled by a gasoline crawler crane and electric locomotive crane with clamshell buckets. First crane dumps oversize stone to hopper of crushing-screening department, and electric crane unloads sand and gravel to truck-loading bins or distributing-plant hopper. All bins have steam coils to heat aggregates in freezing weather. The dry-batching unit has a 2-compartment steel bin of 200 ton capacity. Aggregates are weighed in a 2-compartment 6-ton batcher with automatic attachment, and are discharged directly into trucks. Mixer unit has a 4-compartment steel bin of 300 ton capacity for aggregates in three compartments, and four carloads of cement in the fourth compartment. Bulk cement is power-scooped from cars and elevated to storage bin. Cement is withdrawn from its bin by a screw conveyor to the cement weighing batcher. Batches are weighed into a 3,000-lb. weigh hopper and then discharged to 3-cu. yd. mixer. Deliveries of concrete are made by a fleet of trucks with 4-cu. yd. agitator bodies.—A. J. HOSKIN

Tests of plain and reinforced Haydite concrete. F. E. RICHART AND V. P. JENSEN. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 674-693.—This paper furnishes data on structural properties of poured Haydite concrete. The mixtures include concretes made with fine and coarse Haydite aggregates, natural sand and coarse Haydite, and for comparison, sand and gravel or broken limestone. An initial series of tests was made on beams and cylinders of machine-mixed concrete to secure information on mixes suitable for ordinary reinforced-concrete construction, with particular attention to securing workability, surface finish, and freedom from segregation. The investigation in-

cluded tests on 75 beams, 27 pull-out specimens, and nearly one thousand 6 by 12-in. cylinders. With the consistencies used, no difference was noted in work required to place concrete, or in appearance of the molded surfaces of beams made with gravel, limestone, or Haydite. The gradation and texture of Haydite aggregates required a somewhat greater water-cement ratio than gravel aggregate in similar mixes, and consequently gave a lower strength concrete. Absorption allowance is not fixed, but depends on initial moisture content of aggregate as used. For equal water-cement ratios, strengths of concretes made with sand and gravel, sand and coarse Haydite, and fine and coarse Haydite are very nearly equal. There was no indication that strength was limited by strength of aggregate. The modulus of elasticity of Haydite concrete is markedly lower than that of ordinary concrete of like proportions. The density ranged from 93 to 126 lb. per cu. ft. depending upon the amount of sand present, variation in mixture, and moisture control of aggregate. Up to 6 mo. at least, increase in strength with moist curing is comparable with gravel concrete. Bond and diagonal tension resistance are about the same proportion of compressive strength for Haydite concrete as for gravel concrete.—GLENN MURPHY

CEMENT

About the use of pumice as a raw material for cement manufacture. M. STILLER. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 51-4.—Possibilities for use of pumice as a raw material (instead of clay) are discussed and investigated by synthetic burns with a number of different kinds of pumice and trass. Clinkers were burned in experimental shaft kiln. Analysis of raw and finished products are given. Clinkers show flash sets and need additions of gypsum from 4 to 6 per cent to obtain normal setting properties. Alkali content is high, which fact lowers burning temperature considerably. In a rotary kiln a great part of alkali can be volatilized. Economic importance of these methods is illustrated.—A. E. BEITLICH

Quicker tests of cement and concrete. H. KREUGER. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Several preliminary tests have been made in order to investigate the possibility of deciding quickly (in 1 or 2 days instead of 28 days) if a cement is fit for delivery. Tests have proved that there probably may be a fairly good concordance between the normal crushing strength of cubes by 28 days combined air-and-water curing and by steam-hardening in a few hours. Method may be of some use also by quicker testing of concrete. It, however, is not yet satisfactorily developed, but seems worthy of some attention.—EDITORS N. I. A. T. M.

Portland cement plant in Sonora, Mex., to start production in March. *Pit and Quarry*, Feb. 25, 1931, V. 21, No. 11, p. 20-22.—Wet-process plant of Cemento Portland Nacional, S. A., at Hermosillo, Sonora, is nearly completed with daily capacity of 500 bbl. Abundance of fine limestone and clay occur close to plant will be hauled by motor trucks. Stone will pass through gyratory crushers and will then be conveyed to the mill-feed bin or stored. Raw grinding will be 2-compartment mill, the slurry being pumped to four tanks having pneumatic agitation. Pumps will transfer slurry from the tanks to the kiln feeder. Clinker will be taken by drag conveyor for storage or delivery to finish compartment mill. Gypsum is fed by the same conveyor. Cement will be handled to storage silos by a screw conveyor and a bucket elevator. From the silos, cement will be withdrawn to elevator to packer bin for 2-tube packer.—A. J. HOSKIN

The testing of cements by means of earth-moist and plastic mortars. J. P. LOEVENTHAL. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Former comparative investigations carried out by Danish state testing

house are noted, in which Swiss prism method and common hammer method were used; in continuation, a series of tests dealing with mortars of portland cement, aluminous cement and a Danish pozzuolana cement (Moler cement) is discussed. Test-pieces were made in compact moulds and were of consistencies ranging from earth-moist to fluid. They were tested at 7 and 28 days. It was shown that at both dates strength curves of portland and Moler cements ran fairly similarly, although there was no proportionality. In contrast with this, mortars of aluminous cement, of low water content, showed an increase in strength between 7 and 28 days, while mortars of high water content a fall in strength. The various methods of testing are discussed.—EDITORS N. I. A. T. M.

Chemical action of gypsum and other retarders on portland cement clinker. L. FORSEN. *Zement* (Germany), Nov. 27, Dec. 4, 11, 1930, V. 19, No. 48-50, p. 1130-4, 1155-60, 1184.—Reactions which take place when cement and water are mixed and setting problem of portland cement were studied. Especially effect of different retarders was investigated and explained from standpoint of chemistry of complex compounds. It was found, that chiefly calcium aluminates react with retarding agents. Clinker and cement were agitated with water and amount of alumina, which went into solution was determined by chemical analysis. Isolation of several compounds was possible and these were studied under microscope. Retarding effect of following soluble calcium salts was studied: $CaSO_4+\frac{1}{2}H_2O$, $CaSO_2+2H_2O$, $CaCl_2$, $CaBr_2$, CaI_2, $Ca(ClO_3)_2$, $Ca(IO_3)_2$, $Ca(NO_3)_2$ and $Ca(NO_2)_2$. A number of structural formulas for products which are formed in such reactions are derived. Behavior of mixtures of portland cement and high alumina cements are discussed.—A. E. BEITLICH

The strengths of Swiss portland cement—Die festigkeiten der schweizerischen portlandzemente. M. Ros. Eidg. Materialprüfungsanstalt, Zurich. *Wochenschriift des Niedersteörreischen Gewerbevereines* (Switzerland), April 17, 1930, 4 p.—Greatadvances have been made in the improvement of the strength qualities of cement in Switzerland during the last 50 years. Average tensile and compressive strength on moist rammed 1:3 test mortars increased approximately 4 fold between 1881-3 and 1925. Curves show these increases in strength. High early strength cements are included for recent years. Graphs also show tensile and compressive strengths as well as flexure (bending) at 3, 7 and 28 days. Comparison of compressive and tensile strengths for moist rammed and plastic 1:3 test mortars show that the compressive strengths of the plastic are about 60 per cent of those of the moist rammed at the same ages, whereas, the tensile strengths of the plastic mortars are about 30 per cent greater than those of the moist rammed.—H. G. FISK

Preparation and characterization of dicalcium silicate, tricalcium silicate and tricalcium aluminate. I. WEYER. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 48-51.—In connection with work on reactions between kaolin and lime, it was necessary to prepare chemically pure the following compounds: dicalcium silicate, tricalcium silicate and tricalcium aluminate. (1) Dicalcium silicate was prepared from calcium carbonate and silica in a 2:1 mixture by alternating heating, at 2552° F., cooling and mixing. The two modifications, β- and δ- form were separated by fractionated centrifuging in a methylen iodide-acetylen tetrabromide mixture. Optical constants were investigated by microscope and X-ray analysis. Results obtained are in close agreement with findings of American investigators. (2) Tricalcium silicate was prepared at 3452° F. and was obtained in very pure form after several heat treatments. Free lime was present only in small traces. Optical properties are given which prove again unobjectionable existence of this compound. X-ray determinations were made. (3) In a similar manner tricalcium-aluminate was obtained in well crystallized form. Three tables show lines obtained by

X-ray analysis with relative intensity, and they are compared with results by Brownmiller and Harrington. Sixteen references are given.—A. E. BEITLICH

Small-piece testing for strength of cement mortars—Part 3. SHOICHIRO NAGAI. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), Feb., 1930, V. 33, Supplemental Binding, No. 2, p. 46-7B.—Formula is given for relation between compressive strength of 1:3 cement-sand mortar tested by ordinary test method and compressive strength tested with small cylinder method. Effect of water-cement ratio on compressive strength measured by small-piece testing method is illustrated and discussed for several different cements. Constants of strength formula (derived in previous paper) were calculated and difference pointed out between portland cement, blast furnace slag cement, soliditit, neo-soliditit and high alumina cements. Subject is still under investigation. (cf. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), March, 1930, V. 33, Supplemental Binding No. 3, p. 290-5B; JOURNAL A. C. I., Dec., 1930, V. 2, No. 4, *Abstracts* Sect., p. 99.)—A. E. BEITLICH

Zeolites and cements. HENRI LAFUMA. *Revue materiaux constr. trav. publics*, Jan., Feb., 1931, No. 256, 257, p. 1-5, 45-49.—The first part of this paper presents a study of the zeolites and the hydrated salts of cement. Hydrated aluminates and corresponding double salts occur uniformly as hexagonal crystals, negatively monoaxial. Greatly marked symmetry of these crystals—for such complex substances—and their resemblance to similarly hexagonal crystals of hydrated lime, lead to conclusion that their crystalline structure is determined by only a part of the molecules, namely molecules of hydrated lime (a common constituent). In this way are derived all properties so closely resembling salts of zeolites. This resemblance in structure also results in possibility of numerous solid solutions between all these bodies and furnishes an explanation for widely divergent results obtained by different investigators. If similar properties were to be discovered for silicates of hydrated lime, these crystalline structures would assume an important role in determining hydraulic properties. It would be interesting to establish hydraulicity as a specific property of hydrated salts possessing certain structures. Second part of paper reviews above statement, though limited by scant available knowledge concerning silicates of hydrated lime. A new concept, "the adherence structure," arises to supply a novel interpretation of "hydraulicity" phenomenon. Reference is made to original tests and to researches in different countries.—M. A. CORBIN

Studies on calcium ferrites and iron cements—Part 1. SHOICHIRO NAGAI AND KATSUHIKO ASAOKA. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), April, 1930, V. 33, Supplemental Binding, No. 4, p. 130-3B.—In systematic study of combination between ferric oxide and lime in high lime mixtures such as $3CaO:1Fe_2O_3$, $5CaO:1Fe_2O_3$, etc., determined ferrite with highest possible lime content was determined as $2CaO.Fe_2O_4$ and not $3CaO.Fe_2O_3$. Mixture of $3CaO:1Fe_2O_3$ was heated at various temperatures above 1652° F. and properties of final products, especially their solubility in 0.5 N-HCl, were studied. Dicalcium ferrite $2CaO.Fe_2O_3$ dissolves easily while $CaO.Fe_2O_3$ remains insoluble. Similar results were obtained with mixtures of $5CaO:1Fe_2O_3$ and $2CaO:1Fe_2O_3$. Dicalcium ferrite is easily prepared by heating mixture above 2192° F. It was not possible to prepare $3CaO.Fe_2O_3$ even at temperatures between 2550° and 2640° F. Results of heating tests of mixtures: $3CaO:Fe_2O_3$, $5CaO:Fe_2O_3$ and $2CaO:Fe_2O_3$ are given in tables. (cf. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), May, June, July, Aug., 1930, V. 33, Supplemental Binding, No. 5-8, p. 161-4B, 190-2B, 256-9B, 312-5B; JOURNAL A. C. I., Dec., 1930, March, 1931, V. 2, No. 4-7, *Abstracts* Sect., p. 96, 190.)—A. E. BEITLICH

A study of fourteen brands of standard portland cements and four early-strength cements. C. H. SCHOLER AND L. H. KOENITZER. *Proc.*

A. S. T. M., 1930, Part 2, V. 30, p. 581-593.—Only two or three of brands of cement reported in this paper were included in the 1928 report of Committee C-1 of the A. S. T. M. Data is presented on the relationship between chemical ingredients of each brand of cement, time of set, normal consistency, fineness and specific gravity of the cements, slump and flow tests, density of mix, tensile and compressive strengths of mortars, and flexural and compressive strengths of concretes. The general impression from the data is that of rather unusual uniformity. The principal variation in the different brands was their sensitivity to a small change in water content in the mixes at basic water content and above.—GLENN MURPHY

Canada Cement adapts plant at Hull to wet process of manufacture. W. E. TRAUFFER. *Pit and Quarry*, Jan. 14, 1931, V. 21, No. 8, p. 27-32, 26 ill.—Two years ago Canada Cement Co., began conversion of its No. 3 plant at Hull, Que., from dry to wet process. Stone from quarry is loaded by electric shovel into side-dump cars, hauled to plant by gasoline locomotive, hauled two carloads at a time, up an incline and dumped into jaw crusher. From crusher, stone is fed to hammermill discharging onto belt conveyor and is carried to the 2,200-ton storage. Clay is loaded by a gasoline-electric shovel, hauled by gasoline locomotive and dumped through a grizzly into wash mill. The slip is pumped about 1,800 ft. to basin with traveling agitator. Stone passes to feed bins above two raw-grinding mills, each mill having a 600-h. p. motor. Slurry, with 40 per cent water content, goes to correction basins with mechanical and pneumatic agitators, discharging to mixing basin with a quadruple mechanical and compressed-air agitators, then into storage basin with traveling agitator. Slurry is pumped thence to ferris-wheel feeder of 365-ft. kiln, 11 ft. 3 in. and 10 ft. in diam. A 10 section, single-row revolving cooler surrounds discharge end of kiln. Draft is furnished by two fans. Cooler discharges to two conveyors, to open storage or to the finish-mills tanks. Gypsum is fed to same conveyor. Preliminary finish grinding is with eight ball-mills, final grinding with seven 5-ft. by 22-ft. mills. Cement is screw-conveyed and elevated to 250,000-bbl. stockhouses. Other conveyors and elevators take storage cement to packhouse to packers.—A. J. HOSKIN

Some properties of high alumina-cements from six countries. P. H. BATES. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—High alumina cements (ciment fondu) manufactured in six different countries have been examined for their properties by chemical, petrographic and physical methods. The physical characteristics were determined by strengths in the form of 1:3 standard Ottawa sand tensile briquettes and 2-in. compression cubes. Concrete was also tested in the form of 6 by 12-in. cylinders made from a 1:2:4 mix of gravel. The chemical analyses showed the cements were rather widely different from one another. Petrographic examination showed that alumina was largely present either as $CaO\ Al_2O_3$ or as the unstable form of 5 $CaO\ .\ 3\ Al_2O_3$. The wide variation in composition and the difference in constitution did not result in as great a difference in physical properties as would be expected. The effect of heat generated during setting of cement, and effect of amount of mixing water used was also studied. Increased temperatures during setting resulted in decreased strength. Increased amounts of mixing water resulted also in marked decrease in strength.—EDITORS N. I. A. T. M.

Hydraulic additions and trass-portland cement. S. I. DRUJININ. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Volcanic tuff from the Crimea and diatomaceous earth from tested sources, when ground to fineness of portland cement and added to portland cement clinker, give pozzuolana-portland cement which, when used in hydraulic structures, is more resistant to sea water and acid water than is portland cement mortar. Its mechanical strength after two months hardening in water is equal to that of ordinary portland cement mortar without hydraulic addition, using the same

quantity of sand. The best methods for rapidly determining degree of activity of hydraulic addition, are to estimate the amount of lime it absorbs, and to compare strength of mortars, with and without such addition, under conditions afforded by accelerated hardening of the test-pieces at 80 deg. C. The best method for determining optimum addition of hydraulic material is the above-mentioned accelerated or thermal method. Pozzuolana-portland cement produces a more voluminous paste than ordinary portland for same quantity of sand.—EDITORS N. I. A. T. M.

Clinker shipped 200 miles by water is ground at distributing plant. W. E. TRAUFFER. *Pit and Quarry*, Feb. 11, 1931, V. 21, No. 10, p. 57-61.—Storing and packing plant of Great Lakes Portland Cement Co., Cleveland, O., operates on clinker transported from the Buffalo, N. Y., plant of same company in self-unloading boat. At Buffalo plant clinker coolers discharge to conveyors that distribute clinker to concrete silos which feed to belt conveyor discharging clinker through a telescopic spout on a boom into boat having cargo capacity of 37,000 bbl. Five hours are required for loading, 16 hours for the voyage to Cleveland, and 8 hours for unloading. Same boat also transports cement rock from northern Michigan to the company's Buffalo plant. When unloading, boat's boom conveyor discharges the clinker into the boot of a bucket elevator from which clinker is discharged through split chute to concrete storage silos. Clinker is withdrawn through gates under silos and conveyed to mill building. Gypsum is received in hopper-bottom cars. Clinker and gypsum are ground by 30-ft. 3-compartment mill. Screw conveyors take finished product to cement-storage silos. Cement from storage is conveyed and elevated to vibrating screens, to hoppers, to automatic packers for shipments.—A. J. HOSKIN

The rate of hydration of cement clinker—Part 2 and 3. F. O. ANDEREGG AND D. S. HUBBELL. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 572-578.—Part 2—Direct comparison of hydration rates of partially hydrated commercial portland cements ground under oil checked the rates of material ground in air within 1 per cent. At 9 months the effect of calcium sulfate or calcium chloride on rate of hydration was negligible. Apparent depth of hydration of standard portland cement was 3.54 microns at 1 month, 5.12 microns at 3 months, 7.2 microns at 9 months, and was practically complete at 12 months. A high-early-strength cement and a white portland cement showed more rapid hydration than standard portland cement. Part 3—Depths of hydration were measured for particles of tricalcium aluminate, tricalcium silicate, dicalcium silicate, and calcium ferro-aluminate. Experiments were conducted at room temperatures, and corrections were made for impurities. Calcium ferro-aluminate was added in small amounts to each of the three minerals to see what effect its presence might have on the reaction rates. No definite effect was noted, probably because of great reactivity of compound itself for water. Calcium sulfate was added in part of the experiments. A few mixtures of minerals were observed, including one roughly approximating commercial portland cement. Tricalcium aluminate was hydrated most rapidly. Tricalcium silicate was not far behind, while dicalcium silicate had a comparatively slow reaction rate. Rates for portland cements were between the two silicates at ages up to 7 days. In general, mixtures reacted more rapidly than single compounds, particularly when calcium ferro-aluminate was added.—GLENN MURPHY

The relation between the strengths of cements developed by mortar specimens and concrete specimens. J. R. DWYER AND P. H. BATES. *Proc. A. S. T. M.*, 1930, Part 2, V. 30, p. 598-614.—Data are presented showing the relations between the strengths developed by several portland cements in various concretes, and in small mortar specimens. The cements were selected as displaying different, but not unusual, strength properties. The aggregates

used were standard Ottawa and Potomac R. sands, and Potomac R. gravel, limestone, and blast-furnace slag. Several water-cement ratios, and three different mixes of concretes were investigated. Ultimate strengths were obtained at 1, 3, 7, 28 days, 3 months, and 1 year. Curves showing relation between concretes and mortars at different ages are rather similar, but values of ratio are in many cases far from identical. Ratio of concrete to mortar strengths varied with age, kind of mortar specimen, and kind, grading, and proportioning of concrete. It follows that ratio will also vary for different aggregates available. These tests indicate that no such ratio can be assumed as holding for the same concretes at all ages or for all concretes at the same age. All concretes in one kind of a mortar specimen develop a strength which has a certain ratio to strength of same cement in a certain concrete, but this ratio changes with ages of testing, and with changes in kind, grading, and amount of aggregates.—GLENN MURPHY

Contribution to the problem of hardening of portland cement. FRIEDRICH F. TIPPMANN. *Zement* (Germany), Dec. 25, 1930, V. 19, No. 52, p. 1225-34.—Hydrolysis of calcium silicates of portland cement clinker, when mixed with water, is complete; end products consist of silica gels and calcium hydrate. It is unessential whether clinker is treated with little or much water. In normal cement mortar mixtures products of hydration are different due to high viscosity of system. Needle crystals formed when cement is treated with excess water are calcium hydrates which are not formed when mixtures of normal consistency are present. Calcium hydrosilicates are not formed, neither in crystalline nor in colloidal form, in hardened cement. All calcium hydrates, separated by hydration of cement, are not present in hexagonal plates or columns but show irregular lamellar shape. Unsoundness is not due to crystallization of calcium hydrates but due to amorphous calcium hydrate which is formed in later hardening periods in case of cements which contain uncombined lime. In this period, gypsum has no influence. Hardening is caused by ideal cooperation of colloid silica and crystalline calcium hydrates which are most important constituents in hardened portland cement. This calcium hydrate is the fundamental factor in hardening process. A microscopic method is described which allows observation of hardening process in cement water mixtures of normal consistency. Unsoundness due to gypsum is caused by excessive crystallization of calcium hydrate when amount of colloids present is insufficient. It is possible to make a cement, which is unsound due to lime, sound by addition of gypsum which converts amorphous calcium hydrate into crystalline form. This can be done within small limits. Several microphotographs are given.—A. E. BEITLICH

Belgian cement industry. G. BAIRE. *Revue materiaux constr. trav. publics*, Jan., 1931, No. 256, p. 17.—Belgian cement industry has shown great progress in recent years, as manifested in improvement of industrial processes and in perfection of material used. Proportioning is done with greater care and raw mix before calcination presents a more intimate and homogeneous mixture. Slurry is of greater fineness. Calcination is much more uniform and effective, so clinker obtained is generally of satisfactory appearance. Milling is also done with greater care. Numerous plants, which heretofore manufactured only natural cement, today produce portland, notably in Tournai region. Progress in specifications from 1897 to 1927—date of latest specifications—has contributed to rising standard of product. A number of plants now manufacture a high test cement whose properties are comparable to fused alumina cement. Prof. Batta, of the University of Liége, is authority for the statistical data in the article. Total production of portland cement in Belgium has grown from 250,000 tons in 1890 to 3,200,000 tons in 1929. Cement industry is one of most important industries of the country. As production greatly surpasses the national demand, the greater part of cement is exported. Belgium has been able to create and hold its markets abroad. List includes

32 Belgian plants. To guard interests of the industry, a professional Association of Belgian Portland Cement Manufacturers was formed. It exercises control over the cement products of all affiliated plants. Products are tested at University of Brussels. Of the 32 plants listed 29 are affiliated with the Association, which lends its mark only to unquestionably satisfactory products. The laboratory also is engaged in research work and attempts to popularize the acquired knowledge on cements, mortars and concretes. Abstracts of specifications are appended.—M. A. Corbin

Miscellaneous

Communication from the German material testing institutions. Mitteilungen der deutschen material prufungsanstalten (Germany). Verlag von Julius Springer, Berlin. 1930, V. 6-8.—Part A.—Development of other than Prussian material testing institutions. Includes descriptions of laboratories and equipment at the following Institutions: (a) Technischen Hochschule Darmstadt; (b) Technischen Hochschule Dresden; (c) Technischen Hochschule Karlsruhe, two departments, one for concrete and one for wood, stone and iron; (d) Technischen Hochschule München, two departments, one for building materials and one for mechanics; (e) Bayerischen Landesgewerbeanstalt; (f) Technischen Hochschule Stuttgart. Part B. Technical abstracts.—H. G. Fisk

Light mortars of pumice and Si-Stoff with portland cement. Heinrich Luftschitz. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 55-9.—Properties of cement mortars with pumice and Si-Stoff were examined. One mixture consisted of 1 part of portland cement and 6 parts of pumice (0-0.2 in.) and another one of 1 part of portland cement, 1 part of Si-Stoff and 5 parts of pumice. Si-Stoff is waste product of alum manufacture and contains large amounts of soluble silica. Analysis of Si-Stoff and pumice are given. Mortar with Si-Stoff is lighter, more dense and has better heat insulating properties than first mixture. Its coefficient of expansion is smaller and it is rust preventing. It is suitable for use with steel skeleton structures and for manufacture of light concrete pipes. Mortars for such uses should not contain more than 0.25 per cent water soluble substances.—A. E. Beitlich

Protection of construction materials against chemical and physical agencies. Schutz der Bauwerke gegen chemische und physikalische angriffe. Otto Graff and Hermann Goebel. Verlag von Wilhelm Ernst & Sohn, Berlin, 1930, 224 p.—This book is written from standpoint of engineer and chemist, and illustrations and examples are taken from experiences of the authors. It is not advanced as a comprehensive treatise, but emphasis is placed upon numerous problems encountered in field of construction and engineering. Subjects treated are: natural building stones; cementing materials, i. e., limes and cements (portland, etc.); mortar and concrete; masonry construction which includes concrete, reinforced concrete and refractory construction; metals and wood. Under each subject methods of use, or construction, physical and chemical properties, tests, etc., and known methods of protecting or prolonging the life of the material are given. Emphasis is given the proper selection of material for the service to which it is to be put, and proper engineering design and installation of the material.—H. G. Fisk

Coloring cement. *Conc. Bldg. Conc. Prod.* (England), March, 1931, V. 6, No. 3, p. 44.—Requirements for cement color pigments are color durability under exposure to sunlight and weather, fine subdivision, intensity of color when finely subdivided, and a chemical composition such that pigment does not react with cement to detriment of the color or cement. The most suitable are iron oxides (red, black, yellow, brown) manganese dioxide (black) chromium oxide (green) carbon pigments (black) ultramarine (blue). Use of organic colors is not dependable. Colors containing Prussian blue, cadmium

lithopone and zinc and lead chromates should be avoided. Brilliant or intense colors are not generally attainable. Carbon black pigments although most effective, cause serious reduction in strength and are difficult to incorporate uniformly when quantity exceeds 2 or 3 per cent of weight of cement. Black iron oxide is better pigment but the cost is rather high. Limit of 10 per cent of cement weight is usually put on quantity of pigments used, although experiments show that in certain cases this limit may be safely exceeded. Most satisfactory way of incorporating pigment is to grind with cement. For delicate tints white cement or a mixture of white and gray, should be used, and such aggregates as silica sand and marble. As far as possible the color of aggregates should harmonize with that of the cement paste. Coloring of concrete has been accomplished by penetration processes, but variations inherent in the absorptiveness of the surface usually cause some non-uniformity of color. It is usual to incorporate a fluosilicate hardener with the color producing salt, the solution being applied after the concrete has been cured and allowed to become surface dry. A final oil wax treatment is applied to fix and protect the color.—JOHN E. ADAMS

PROPERTIES OF CONCRETE

Protection of structures against chemical and physical attacks. "Schutz der bauwerke gegen chemische und physikalische angriffe." OTTO GRAF AND H. GOEBEL. 1930, Wilhelm Ernst and Son, Berlin (Germany), R. M. 22.00. Reviewed in *Zement* (Germany), March 26, 1931, V. 20, No. 13, p. 306.—Authors report in this book various kinds of destructions of structural materials and structures. Effect of chemical and physical conditions is shown by test results, tables and illustrations. Of special value are descriptions of restorations of entire structures showing useful application of experience.—A. E. BEITLICH

Effects of contraction in large concrete dams. ALBERT RENAND. *Magazine Technico* (Argentina), Sept.-Dec., 1930.—Engineers of concrete dam at Saint Marc on Thourian River having in mind dangers arising from formation of contraction cracks in concrete dams have made very careful observations on formation of cracks in that structure during construction. San Marcos dam is gravity type about 140 ft. high and contains approximately 80,000 cu. yd. of concrete. Work was authorized in August, 1928, and first cracks were observed in October, 1929. A number of other cracks were noted later and the progress of these cracks and their location in the structure is given in detail. Colored water was used to trace the penetration of the cracks —C. G. CLAIR AND M. N. CLAIR

Studies on laitance of cement mortars and concrete. SHOICHIRO NAGAI AND KOSUKE YOSHIZAWA. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), Jan., 1930, V. 33, Supplemental Binding, No. 1, p. 19-21B.—In continuation of previous work relations between compositions of laitance and water-cement ratios, admixtures or accelerators were studied. (1) Cement mortars. Results of analyses of laitance formed on 1:2 cement-sand mortars were compared with cements used. Increase in loss on ignition and lime show formation of large amounts of calcium carbonate due to carbonation of calcium hydroxide which was formed during hydration process. High SO_3 was found in cases of large w/c ratios. (2) Neat cements. Similar relations as in (1) were detected. (3) Neat cement with admixtures or accelerators. Siliceous earth, pozzuolana, lime, calcium chloride, "Cal" and gypsum were mixed in different proportions with 2 cements and their chemical composition studied. Amounts of water soluble chlorine and SO_3 were determined. —A. E. BEITLICH

Studies on laitance of cement mortars and concrete—Part 2. SHOICHIRO NAGAI. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), July, 1930, V. 33, Supplemental Binding, No. 7, p. 260-2B.—Results of analyses of chemical compositions of laitances formed on various concrete works using portland cement and of mortars of blast furnace slag cement and high early strength alumina cement are reported. (1) Amount of laitance on 1:2:4 concrete increased with w/c ratio. Laitance on concrete with small w/c ratio was nearly equal in composition to cement while laitance formed with large w/c ratio contained larger amounts of lime in comparison to silica. The SO_3 content increased with w/c ratio. (2) Laitance on field concrete contained large amounts of fine sand. (3) Considerable amounts of SO_3 (5 to 6.5 per cent of ignited sample) were found in laitance formed at concrete pipe making. (4) In laitances formed on high alumina cement (Ciment fondu) and blast furnace slag cement considerably larger quantities of alumina (hydrated alumina from aluminates) were found.—A. E. BEITLICH

Resistance of concrete to high temperatures. (cf. *La Journée Industrielle*, Dec. 20, 1930.) *Le Constructeur de Ciment Armé*, Feb., 1931, No. 137, p. 36.—It has been noted that reinforced concrete construction withstands fires better than steel frame structures. Highly infusible nature of cement and aggregates and no oxidation of exposed steel are advantages of concrete construction. Aside from fusibility, the compressive strength was also considered in tests made in Germany. Parallel tests of portland and slag cement mortars were carried out. Between 500° C. and 900° C., the two mortars showed similar trend of compressive strength. On the other hand, from ordinary temperature up to 300° C. slag cement mortar shows an increase in strength, while portland cement mortar shows a decrease of 10 to 20 per cent of strength values. Between 300° C. and 500° C., strength values show a decrease less rapid in the case of slag cement mortar. Exceptional heat-resisting qualities of slag cement justify use of slag as ingredient in the cement. These considerations are of interest not only in connection with fires, but in all cases of local heats encountered in the industrial processes of today.—M. A. CORBIN

Pre-determination of the composition of concrete necessary to attain a given strength and elasticity. M. ROS. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930. The formula given by Feret enables the strength and elasticity of concrete in compression to be predetermined with sufficient accuracy for practical purposes. It enables recognition of technical and economic possibilities of producing a concrete of definite and suitable quality, consistency, workability, porosity, strength and elasticity. By making use at same time of cement tests with plastic mortar according to Feret's method the whole of the wide field presented by the cement industry is governed by a unified idea. Feret's prism method enables the energy of the cement, the characteristic of the sand and gravel, and the strength properties of the concrete to be determined. In practice the prism compression strength is to be considered as correct strength for concrete. Curves for most favorable intergranular arrangement lie in the area bounded by the Fuller curve and the curve obtained by the Swiss Federal Testing Laboratory (E. M. P. A.).—EDITORS N. I. A. T. M.

Compression, tension and bending tests, cement and concrete. A. T. GOLDBECK. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930. Present practice and trends in methods of making strength tests on cement and concrete in the United States of America are discussed. It is indicated that although the 1:3 mortar briquet, made with Standard Ottawa sand and tested in tension is now standard, there is difficulty in obtaining concordant results in different laboratories. Although the compression test is still most universally used as a standard strength test for concrete, there is a

growing tendency to employ beam tests where high crossbending resistance is important as in highways. Method of making beam test has not yet been standardized.—EDITORS N. I. A. T. M.

Cement and concrete. R. M. STRADLING. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—In a report dealing principally with work carried out at the Building Research Station, Garston, England, a section on strength describes work done on effect of water-cement ratio on strength, recent increase in strengths obtained from rapid-hardening portland cements and relation between crushing strength and modulus of elasticity. Under heading of shrinkage, work on stress distribution along a reinforcing bar, influence of type of cement, percentage of reinforcement and conditions of storage are discussed. A note on the creep of concrete under load, mentions work by Faber, and briefly outlines the program of research in hand at Building Research Station. Joints in concrete and, lastly, resistance of concrete to chemical action, on which work is being done in collaboration with the Institution of Civil Engineers, also receive attention.—EDITORS N. I. A. T. M.

The crushing strength, density and water-cement ratio of concrete and mortar. E. SUENSON. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—The following investigation shows that: (1) Except that the exponent 2 can vary between 1.8 and 3.5, confirmation has been obtained for Feret's formula for plastic mortars, viz: $S = K \cdot T^2_k$, where S is the crushing strength of the mortar, T_k the density of the plastic mass, and K a constant depending on the quality of the cement, the conditions of storage and the age of the mortar. (2) In the form: $S = K \cdot T^n_k$, the equation can be generalized so as to be valid for all consistencies, from the driest to the wettest, provided the determination of T_k is postponed until solidification has occurred. (3) n has the same value for air and water storage. The reason it varies in magnitude as described in (1) remains at present unknown.—EDITORS N. I. A. T. M.

Laboratory tests and control and practice on the building site. M. SPINDEL. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Concrete of any desired quality can be rationally and with certainty produced if due heed is given to our knowledge of the testing of materials. Otherwise, concrete structures, like other structures, can show serious defects. In addition to determining strength and density, tests must be made to ascertain the expansion and shrinkage due to the rise of temperature in setting and variation of air temperature, and the resistance to frost, to attack by water, and to wear. Dam walls must be rendered impermeable by concrete facing. For the attainment of strength and density, the utmost importance is to be attached to cement, aggregates, amount of water, and method of working. The effect of these factors on the quality and cost of the concrete can be indicated by representing cement, aggregates, water and air on the Spindel four-component parallelogram.—EDITORS N. I. A. T. M.

Shrinkage of mortar and concrete. E. V. MEYER. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—A series of experiments was undertaken to elucidate the shrinkage of light concrete, especially the so-called cellular concrete. As is well known this material is produced by mixing together a cement paste and a foam. To attain sufficient strength in this material (which is produced with a density varying from 16 to 70 lb. per cu. ft.) a relatively rich cement mortar must be used, which results in serious shrinkage on drying out. The importance of the various factors which affect this shrinkage is investigated, and the results are as follows: (1) Type of Cement. As was to be expected, there are important differences between various cements. Finer grinding of the same cement gives rise to more pronounced shrinkage. (2) Mixing proportions. By increasing the amount of added sand, the shrink-

age step by step diminishes. This decrease is quite regular for cellular concrete, and the author has advanced a formula for the shrinkage of cellular concrete of different proportions. (3) Added Water. It is established that the shrinkage is increased by increasing the amount of water used. (4) Foam Liquid. The foam liquid has no effect on shrinkage. (5) Storage. Keeping the concrete wet over a long period, followed by intensive drying, increases the ultimate shrinkage; shrinkage is diminished, on the other hand, by mild drying out. The shrinking of cellular concrete products is investigated. Finally it is shown that treatment of the material with saturated steam at 100-180 deg. C. results in a considerable reduction of the shrinkage.—EDITORS N. I. A. T. M.

Influence of frequently repeated load on the formation of cracks and the cracking—Safety of reinforced concrete beams—Einflusz haufig wiederholter Belastung auf die Riszbildung und Riszsicherheit von Eisenbetonbalken. HEIM. *Dissertation an der Technischen Hochschule Karlsruhe* (Germany), 1930, 71 p.—In the first section the author reviews previous investigations. Second part takes up special subjects such as effect of variation in speed of application of load, apparatus, test specimens, and preliminary tests. Third section deals with static loading of reinforced concrete beams and includes measurements of elasticity and determination of tension on columns and beams. Formation of cracks in reinforced concrete beams is also taken up. The fourth section treats the effect of frequently repeated load and includes the investigation of concrete beams with and without reinforcing. Conclusions include: (1) Young concrete under frequently recurring load attains a permanent deformation which exceeds the elasticity. (2) A repeated load which does not exceed half of the static load causing cracking, will not cause cracking even after one million load cycles. With a load equal to three fourths of that causing cracking under static loading, cracking will occur under repeated load. (3) If cracks have already appeared under a certain static load, on changing the same load to a constantly repeated load, a condition of equilibrium will be attained in the cracks before the millionth load cycle is reached.—H. G. FISK

Comparative study of the strength of mortar and concrete under tensile, bending, shear, indentation and compressive stresses. R. FERET. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—The author refers to and confirms the fact that it is first necessary to distinguish between two classes of fundamental resistances, firstly, resistances to compression, indentation and shear, which are proportional to each other, and secondly, resistances to tension and bending, which are also proportional to each other, but bear no fixed relation with the first class. Author then shows, both from personal experience and from analyzing minutely the results of various other experimenters, that in general, for series of mortars and concretes made with the same cement and differing in only one factor, resistance to tension (or to bending) increases less rapidly than the resistance to compression, and varies approximately with 2/3 power of the latter. Otherwise for mixtures of various composition, ratio between first and second of these resistances is approximately proportional to that between the quantities of water and cement used. Disagreement between two classes of resistance is due principally to fact that surface layers of test pieces, which are of first importance in rupture under tension and bending, seldom have same composition as the core. This is due as much to unequal distribution of materials against the walls of the mold and in interior, as to a hardening which varies for various regions, according as the surrounding conditions have a more or less direct influence. Apart from this, resistances are variously influenced by various internal stresses which vary according to distance from free surface, and which result from changes in volume due to chemical, thermal and hygroscopic action. It seems, however, that the tensile and bending tests do not give very accurate information regarding similar forces to which concrete is sub-

jected in practice, although the figures given by compression tests are fairly proportional to the actual strengths.—EDITORS N. I. A. T. M.

Cracks in concrete. M. E. ROSSBACH. *Revue materiaux Constr. Trav. Publics*, Jan., 1931, No. 256, p. 12-17.—Development of cracks in plain and reinforced concrete is consequence of shrinkage of cement and of the low resistance of concrete to elastic stresses, other than compression. As, due to foregoing, concrete is depended upon only in its resistance to compression, its other properties are frequently neglected and a concrete is classed entirely in accordance with its compressive strength. Our daily experience shows failures of concrete in compression are rare, in spite of unreasonable loadings and irrational proportioning of materials. Using standard portland cement and an aggregate of river origin or of porphyry, gives concrete well able to resist usual stresses with required safety. Yet cracking of concrete occurs all too frequently and is main grievance against this material. While compressive strength remains the primary requisite of concrete, attention should be paid to its other qualities. A ductile concrete, least affected by cracking and friction, should be sought. The deplorable appearance of cracks on structures, the menace to life of structure and to reputation of reinforced concrete in general should be kept in mind.—M. A. CORBIN

The cause of poor agreement between tensile strength of neat cement and sand mortar strength. KATSUZO KOYANAGI. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), Nov., 1930, V. 33, Supplemental Binding, No. 11, p. 425-7B.—Experiments by R. Meade, G. Haegermann and J. Iguchi are discussed. Based on author's investigations, strength of neat cement is just as much affected by amount of mixing water as is mortar strength. Best results in each case are obtained with a certain fixed quantity. Cements which pass water test but not boiling test have in general very high tensile strength in neat specimens and low sand mortar tensile strength. Fineness affects strength of neat cements: coarse samples show in general greater tensile strength than fine cements (while mortar strength is mostly improved by fine grinding). Factors which increase strength of neat cement have adverse effect on mortar strength.—A. E. BEITLICH

Shrinkage of concrete in actual structures. WILLIAM M. BASSETT. *J. Boston Soc. C. E.*, March, 1931, p. 67-81.—Change in volume of concrete must be expected and New England Power Construction Co., has tried to design the Fifteen Mile Falls Lower Development so as to reduce the damage from such volume changes to a minimum. Spillway structure was poured in sections 45 ft. long after a study taking into consideration the possible shrinkage of the concrete as 0.055 per cent of its length, curvature of the bulkhead plant, restraint of bed rock and capacity of concreting plant. A field survey made approximately one year after pouring of concrete showed six out of eight of the 45-ft. sections had intermediate cracks. The cracks appeared in less bulky sections and indicated that if sections something less than 30 ft. long had been used, intermediate cracks would not have formed. Spillway channel slab used for protection of earth bank of spillway channel was built on concrete ribs spaced about 20 ft. centers. Elimination of irregularities on the surface was important as water velocity is high and slabs were therefore designed with 0.5 per cent steel to prevent cracks forming. Recent field examination shows a crack between slabs and ribs and also between slabs and toe beam. Theoretical width of cracks between slab and rib is 0.06 in. and actual width was found to be about same. Theory in design and procedure in construction of intake structure are described in detail. Every effort was made to anticipate and overcome effects of volume change that might result in a crack through which seepage would occur.—MILES N. CLAIR

The strength of Swiss portland cement. (See Materials—Cement.)

Engineering Design

Bridges

Longest multiple-arch concrete highway bridge to span Susquehanna river. Charles M. Nelson. *Eng. Con.*, March, 1931, p. 119-122.—River crossing between Columbia and Wrightsville, Pa., has a total length of 7,374 ft., including approaches. The spans of bridge are on a tangent with exception of first span on each side. The river structure consists of 28 concrete arches with three ribs each spaced 17 ft. 9 in. on centers, parabolic intrados and extrados, rise of 32 ft. and 27 ft. 4 in., respectively, and a clear span of 185 ft. The rib section is 7 ft. wide and varies from 3 ft. 10 in. at the crown to 7 ft. at the springing. Each span is divided into 11 panels by transverse spandrel walls. Arch ribs are joined at alternate panel points by concrete struts. Floor system is carried on concrete spandrel columns 2 ft. 6 in. by 4 ft. along the line of outside ribs and 2 ft. 6 in. by 3 ft. 6 in. along the line of the inner ribs. Floor panels are formed by longitudinal and transverse floor beams and are 16 ft. 10 in. by 17 ft. 8 in. Floor slabs are of two-way reinforced concrete. An unusual feature in the floor design is the arrangement and design of expansion joints. Super-structure will be completely separated by open joint 1½ in. wide in floor system and 1 in. in railings at center of first and fourth panels from each abutment or pier. Thus each arch floor system will be cut at four points between piers. Joints are to be filled with bituminous filler and flashed with copper. Roadway is 38 ft. between curbs. There is one 6-ft. cantilevered sidewalk. The approach structures consist of 18 50-ft. concrete girders and two 80 and 85-ft. steel girders, all on concrete piers.—N. H. Roy

Buildings

Design of a 15-story apartment building in Vienna (Austria). *Zeitschrift Oester. Ing. Arch. Vereins* (Austria), Jan. 9, 1931, V. 83, No. 1-2, p. 1-2.—New reinforced concrete skeleton structure of unique design rests on one single reinforced concrete slab foundation. First and second floor are occupied by stores and offices. Apartments are located from third to tenth floor and restaurants occupy tower structure.—A. E. Beitlich

Storage building with precast roof arches. Mangold. *Beton u. Eisen* (Germany), Jan. 20, 1931, V. 30, Heft 2, p. 37-38.—The city of Munich received 37 competitive designs in reinforced concrete, steel and timber for a storage shed for iron water pipes. Reinforced concrete design of Wayss & Freytag A. G. was selected as most satisfactory and most economical. Building is a one-story structure 345 ft. long by 76 ft. wide and 56 ft. high. A crane runway extends the length of structure and 69 ft. beyond, spanning the adjacent street. The girders are roughly I-shaped and carry the crane rail on the lower flange. Girders are about 12 ft. deep with a web thickness of 1 ft. 4 in. and a chord thickness of about 4 ft. They are carried by supports spaced at 69 ft. and with these supports form a series of three three-legged bents along each longitudinal wall. These bents are connected by hinges in the crane girders. Arched roof members, about 1 ft. 6 in. deep with a rise of 15 ft. 9 in. and spaced at 8 ft. 7 in., were precast on the ground and lifted into place by crane. Crown reinforcement was designed to act somewhat as a hinge, and this section and two ends of arch were not concreted until arch was in place. Alternate arches were provided with tie rods to take up horizontal thrust. A reinforced member

extending the length of structure connected arches at crown. The light weight concrete slab between the arches also exerts a stiffening effect. Only scaffolding necessary for roof was a line of timber framing along center of building, supporting crown. Skylights are built between the arches and stop about 10 ft. short of eaves. Glass area is 25 per cent of total roof area. To enable loaded crane to pass out of building a sliding panel between the crane girders and a large folding door are provided at one end.—A. A. BRIELMAIER

DAMS

Cellular corewalls for embankment dams. H. C. HOWELL. *Eng. News Record*, Feb. 26, 1931, V. 106, No. 9, p. 359.—A new type of cellular concrete corewall for embankment dams has been developed by Mexico office of the J. G. White Engineering Corp., consisting of a row of vertical arched cells each of which drains into a longitudinal conduit at the base. Conduit discharges into outfall drains at convenient places. Important features are (1) downstream portion of dam is kept dry; (2) cells and drains permit inspection; (3) cells form stiffer structure than a solid wall (4) arched sides are more economical than flat ones because tensile stresses and necessity for reinforcing steel are eliminated. The idea for the cellular corewall was put into practice in 1917 to 1919 in the construction of the Requena Dam about 50 miles from Mexico City.—D. E. LARSON

Design and economy of concrete and reinforced concrete dams. E. PROBST AND F. TOELKE. *Zeitschr. d. Vereins deutsch. Ing.* (Germany), 1930, V. 74, No. 13-15, 15 p.—Paper, which was presented at second world power conference in Berlin (Germany), 1930, pictures present state of dam construction considering especially safety and economy. Ways are shown to prevent failures. In general, curved form of gravity dams does not increase stability of structure unless contraction joints are filled and treated in manner similar to that in construction of Pardee dam (cf. *Eng. News Rec.*, Feb. 14 and March 21, 1929, V. 102, No. 7 and 12, p. 258-62, 457-8). Study of cross-sections of numerous dams shows predomination of triangular type. Relation between width of dam at bottom and total height is characterized. Development of arch dams is illustrated. Corfino and Turrite dams in Italy are of elastic arch type. Latter dam has constant outer radius of curvature. Wall at crest is 13.8 ft. thick at center and this dimension increases to 19.7 ft. at both sides. As examples of constant angle arch dam type are described Big Santa Anita, Pacoima and Diablo dams (cf. JOURNAL, A. C. I., Sept., 1930, *Proceedings*, p. 1-64). Latter has two gravity abutments. Attention is called to gradual thickening of foundations on downstream side of dams. Mesnager builds a number of arch dams, decreasing in height, between each two of which a water reservoir is formed. Walls can be built relatively thin. A new type of dams designed by authors is described. Its lower part is of gravity type while upper part is arch structure. Gutzwiler, Figaro and Ziegler systems are sketched. Concrete structure of Stony Gorge dam in California is of Ambursen type. (cf. *Eng. News Rec.*, July 11, 1929, V. 103, No. 2, p. 46-51.) Main advantage of this type is even distribution of loads on underground. Buttress spacing over 18 ft. is not economical. Big Dalton dam is described as an example for multiple arch type dam with double wall buttresses (cf. *Eng. News Rec.*, Dec. 26, 1929, V. 103, No. 26, p. 994-7). Formation and causes of cracks are discussed in connection with those structures. Third part of article deals with safety and economy and gives general directions concerning foundations, calculations, structural materials and recommendations for research work in dam construction. Great emphasis is placed on temperature measurements in interior of large concrete masses.—A. E. BEITLICH

Gravity dams arched downstream. B. J. LAMBERT. *Proc. Am. Soc. C. E.*, March, 1931, V. 57, No. 3, p. 425.—It has been a common practice to arch masonry gravity dams upstream with the thought that additional factor of safety was introduced by arch action. When walls of canyon are not sufficiently rigid to support thrust, there is no gain from arch plan over a straight gravity dam. In such cases stability of a straight gravity dam against overturning may exceed that of a gravity dam of same section that has been arched against water load and a dam arched downstream may have a stability that exceeds either. In illustrating this point the author makes use of measurements and calculations from a 1/240 scale model of the late St. Francis Dam. In his analysis he treats the structure as a unit and shows that the portion of dam about which overturning would occur (the pivot) lies farther from the centroid for gravity section than for section arched upstream and farther for section arched downstream than for either. Length of dam that can act as a pivot again favors reverse arch. The objection that reverse arch plan would tend to open up rather than close joints is considered and it is suggested that anchored eyebar chains under initial stress could be embedded in concrete of dam to develop any desired initial compression in the concrete. While admitting unorthodox nature of recommendations the writer urged that in any case preliminary studies should be made on a model of proposed site and structure.—H. J. GILKEY

Problems in concrete dam design. D. C. HENNY. *Eng. News Record*, March 12, 1931, V. 106, No. 11, p. 431-435.—Wide differences of opinion regarding fundamentals of safe and economical design of concrete dams still exist. Danger inherent in uplift is now thoroughly realized by dam designers and builders and means of reducing its effect are: roughening rock base and concrete surfaces to increase adhesion and resistance to water creep and sliding; grouting foundation; introducing drains in foundation and mass concrete; inclining or stepping construction joints upwards in downstream direction; using water stops in these joints near upstream face. Grouting upstream toe of dam does not guarantee against uplift but helps to diminish it. Drains in foundation rock and in concrete are now commonly provided, but requirement that these be straight and accessible is too often neglected. Principal cause for extensive cracking in large dams may be tendency of cement manufacturers to increase fineness of grinding. This affords advantages in workability, early strength and form cost, but in mass concrete important effect is greater heating and consequently an increased liability to cracking. Heat control may be effected by amending cement specifications. Another method of heat control consists of artificial cooling of interior by water circulating through pipes. Problem of heat stresses and cracking in dams can be solved by use of precast concrete blocks. This would reduce cost of form work, but cost of handling would be high.—D. E. LARSON

MISCELLANEOUS

Stands of novel design at English race course. *Concrete*, Feb., 1931, p. 95.—The stands at Northolt race course are of steel and concrete. The roof deck is carried by cantilevers of steel encased in concrete. Cantilevers extend 60 ft. forward from the back of the stand.—N. H. ROY

Short-cuts in structural design. JAMES R. GRIFFITH. *Concrete*, Feb., 1931, p. 45-48.—Unbalanced reinforcing is discussed for the case of concrete beams and slabs whose dimensions have been determined by considerations other than that of producing maximum allowable stresses in both concrete and steel. A chart is given for determining actual concrete stress and area of steel required, for a breadth of 12 in. and f_s of 18,000 lb. per sq. in. A second chart is for f_s of 20,000. Three values of n are given.—N. H. ROY

Calculation tables for hollow concrete brick ceilings. HANS KORF. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 61-3.—A graph is described which enables one to read directly thickness of bricks, total thickness of ceiling and size of reinforcing when span, load and type of support are given. Several examples explain use of graph. It can be applied to ceiling systems by Ackermann, Kleine, Wenko and Remy. Reverse reading of table gives greatest span for certain ceilings of given dimensions.—A. E. BEITLICH

Structural design and construction of concrete improved in 1930. *Concrete*, Feb., 1931, p. 16-18.—A very interesting bibliography of technical papers, results of tests, committee reports, and contributions to the field of design for the year 1930.—N. H. ROY

Concrete bulkheads for creek channel improve Jacksonville swamp area. *Eng. News Record*, Jan. 8, 1931, V. 106, No. 2, p. 70-72.—The unsightly Hogans Creek Swamp at Jacksonville, Fla., has been changed to an attractive waterway built of concrete as result of a $500,000 improvement program recently completed. Design of channel structure finally adopted provides for a box 20 ft. wide on two rows of wood piling, 18 ft. apart, with piles driven on 5-ft. centers. A 6 x 8-in. cap runs longitudinally over top of each row of piles. Precast concrete T-beam struts span the two rows of piling on 5-ft. centers. Each end of the struts carries a 6 x 8-in. longitudinal wooden stringer, and upon these stringers rest precast slab units that form sides of box. Two-in. planking is then placed longitudinally under the struts and the bottom of the box is filled with sand to the depth of 2 in. above the top of the strut, which provides a porous floor system for admission of groundwater to channel. Bulkhead panel lengths vary from 6½ to 9 ft. and are precast in 2-, 4-, and 6-ft. widths. The 6-ft. widths are used generally except on curves. Gang molds are used in casting yard where bulkhead panels and T-beams are cast. This yard permits casting of 150 lin. ft. of bulkhead and 21 T-beams at same time. A central mixing plant provides all concrete for the job, for both precast and cast-in-place work. A minimum strength of 3,000 lb. is specified and obtained under laboratory conditions.—D. E. LARSON

Reinforced concrete. S. M. DIXON. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Exact knowledge of the properties of concrete especially in reinforced concrete structures is meager. Innumerable tests on compressive strength of concrete have little advanced accuracy in design of reinforced concrete beams. Experimental work on shrinkage, expansion, modulus of elasticity and plastic yield is still needed. Disintegration of plain concrete under repeated loading makes continued security of some reinforced concrete structures problematical. Engineers are much interested in stresses induced in steel during setting of surrounding concrete, and tests so far are hardly conclusive. Recent design has been much influenced by special light aggregates or by using aerated cement.—EDITORS N. I. A. T. M.

Tests on reinforced concrete structures. R. SALIGER. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—In the years 1927-1929 the following tests were suggested by the writer of this report and performed at the Engineering Testing Laboratory of the Polytechnical Institute of Vienna. In 1927 tubes for the power-station of Blumau and also a new shellroof system, suggested for the barrelwashing-shop of the brewery of Schwechat, were tested. Both these series of tests were performed on full-sized models. In 1928, experiments were carried out on concrete beams reinforced with Isteg-steel. They showed the influence of two round iron bars twisted cold, while during twisting the ends of the bars are rigidly held in their places. These experiments were followed by tests on beams of concrete, reinforced with high-quality steel, and others on pillars of concrete reinforced with cast iron and corded with steel. In 1929 a series of tests on concrete pillars reinforced with high-quality steel, yielded important results.—EDITORS N. I. A. T. M.

Combined compression and bending in reinforced concrete. E. M. ROYDS-JONES. *Concrete Constr. Eng.* (England), Feb., 1931, V. 26, No. 2, p. 144-149.—Charts are given for determining thickness of concrete and amount of reinforcing steel necessary in slab or beam subjected to combined bending and compression for cases where concrete is not stressed to a specified allowable stress. This is the case where the size of member is fixed already by other considerations. Example shows application of charts. Total moment of external forces about steel is obtained for beam of known dimensions, bending moment and end compression. Then $H = M/bd^2$, where M = moment of forces about steel, b = width and d = depth of beam. From graph value of stress in concrete obtained for calculated value of H and selected value of stress in steel. Curves are given for different stresses in steel. With value of stress in concrete thus obtained a second graph gives values of k (ratio of depth to neutral axis, to depth to steel) for given allowable stress in steel. Then compressive stress in concrete $= 1/2 f_c kbd$, tension in steel and required area of steel are obtained. Examples illustrate the usual general case, case where concrete dimensions are too small, and where no tensile steel is required.—JOSEPH MARIN

Deformation of the reinforcement as a measure of its value in ferro-concrete. E. H. F. EMPERGER. *First Communications of N. I. A. T. M.* Group B, Zurich, 1930.—Investigation of ferro-concrete has been limited to measurements under permissible load and determination of breaking loads. The connection between the two has been represented by a theory which cannot be regarded as free from objection: that enclosed steel is constrained to deform with the concrete, and that the measurement of this deformation in the case of the reinforcement of a beam in tension enables the stress taken by this reinforcement to be determined, so that the variation of the quantity n as load increases can be evaluated. The relationships under compression are much simpler. Parallel experiments on concrete columns, with and without reinforcement, are used to determine the increase in strength due to the reinforcement under same deformation of concrete. These tests show that reinforcement which is not proof against buckling does not withstand compression as well as the surrounding concrete. The feeble round steel rods yield sideways, and do not contribute to the strength of the member to an extent corresponding to the magnitude of their deformation, even when they are held within a circular reinforcement. The most important result of this research is that by the use of a buckling-proof reinforcement of cylindrical profile, within a circular reinforcement, full utilization can be made of the strength of the steel under compression up to the yield point, with similar utilization of the concrete. It is also possible in this way to utilize the much higher yield points of high-strength steels.—EDITORS N. I. A. T. M.

Solution of statically indeterminate structures by Begg's method. K. SCHOECHTERLE. *Beton u. Eisen* (Germany), Nov. 20, 1930, V. 29, Heft 22, p. 406-410.—In brief review of theory and application of Prof. Begg's mechanical method of solving statically indeterminate structures, the last section describes experience of Stuttgart office of Bridge Dept., German Government Rs., with this method. This office, in 1927, designed and erected a concrete arch bridge at Weikersheim, with a span of 90.0 ft. and a rise of 27.6 ft. It was decided to compare results of a mechanical solution with completed analytical analysis of this structure. Preliminary tests with models bearing a size ratio of 1:25, 1:50 and 1:100 to the original structure showed that the 1:50 ratio was most satisfactory for this arch. A model in 0.08 in. was accordingly made in this size ratio. Influence lines comparing results of analytical and mechanical solutions for moments, shears and thrusts at crown and springing show remarkably close agreement. In this case mechanical solution must be considered equal to analytical. Thorough and critical investigation made of this method led to conclusion that it is applicable to practical use.—A. A. BRIELMAIER

Nomogram for calculating the compressive and tensile stress produced by a force acting on a rectangular section. JORGE QUIJANO. *Ingenieria* (Mexico), Jan., 1931, V. 5, No. 1, p. 8-9.—An alignment chart, one of a series of value in design of concrete, for determination of stress at any point on a section subjected to a force perpendicular to that section, acting on an axis of symmetry. Left hand scale or line $\frac{12\ pr}{a^2}$ intermediate scale R; and right hand scale P/ab all in metric units. a and b are dimensions of the section on which the force P acts. p and r are abscissa respectively of point where force P intersects section and of point where stress R is desired.—C. G. CLAIR AND M. N. CLAIR

Nomogram for calculating the unit shear by means of bending moments. JORGE QUIJANO. *Ingenieria* (Mexico), Jan., 1931, V. 5, No. 1, p. 16-17.—An alignment chart, one of a series of value in design of concrete, for the determination of shearing stress at any section of reinforced concrete beam. Left hand line or scale bd; intermediate scale $\frac{M_A - M_B}{S}$ and right hand scale u. b and d are the dimensions of the section, M_A and M_B the moment at points distant S apart and u is unit shearing stress, all in metric units.—C. G. CLAIR AND M. N. CLAIR

Short cuts in designing reinforced concrete beams. ODD ALBERT. *Civil Engineering*, April, 1931, V. 1, No. 7, p. 635-37.—The amount of work involved in the design of concrete structures may be reduced either by using more simplified formulas or by use of tables and charts. Formulas are presented for rectangular beams in a simplified form making it possible to solve for depth with one movement of slide rule runner. Charts for the design of beams and flat slabs of reinforced concrete are also presented. In working out these formulas and charts, it was assumed that variation of stress to deformation of concrete in compression is a straight line and concrete in tension was neglected.—D. E. LARSON

Circular culverts. W. S. GRAY. *Concrete Constr. Eng.* (England), March, 1931, V. 26, No. 3, p. 213-219.—Uncertainty of distribution of loading on an empty culvert or subway is pointed out. Upward reaction differs according to method of construction adopted. There may be a uniformly distributed upward reaction, line contact and concentrated reaction, or a reaction distributed over a saddle in contact with a segment of pipe. In small culverts the reinforcement will generally be the same at all parts. Expressions given for combining moments due to uniformly distributed downward, upward, and lateral loads, moments due to active earth pressure can be found. Expressions are given for case of loads concentrated at opposite ends of vertical diameter. Moment thrust and shear for any section are obtained, similiar to calculations for stresses in a circular ring. Castigliano's principle of least work is applied neglecting the internal work due to normal and shearing stresses. Expressions are given for bending moment and thrust for any point due to the dead load of pipe and for uniformly distributed load. Curve shows variation in moment coefficients along circumference of pipe. Curve also plotted showing variation of thrust coefficients along circumference of pipe. Expressions for moments and thrusts are given for cases of two radial forces symmetrically arranged and of two vertical loads symmetrical about vertical axis of pipe.—J. MARIN

ROADS AND PAVEMENTS

Concrete street construction in Camlenwell, Victoria. C. M. P. NEYLON. *Commonwealth Engineer*, Dec., 1930, V. 18, No. 5, p. 188-193.—Following a visit of S. M. Goldsworthy to America in 1924, the council has undertaken an extensive program of concrete street construction. Concrete

roadway is 20 ft. wide between curbs which are 6 in. wide and 6½ in. high (to permit of 2-in. surfacing of asphalitic concrete at a later date). Crown is 3 in. and thickness of roadway 7 in. Foundations are prepared by mixing ashes and sandy loam 3 in. thick and adequate drainage of the subgrade is insured by drains. Importance of reinforcements at weaker points as corners, joints, etc., is stressed. Thermal expansion and that due to variations in water content were allowed for at the rate of ½ in. per 100 ft. Joints were made slightly wider in the curbs. The mix was 1:5.6 by volume, based on Abrams' fineness modulus but was altered to suit variations in material. Slump was about 1 in. and gave 28-day strengths of 3,300 to 3,800 lb. per sq. in. Screeding was done against the grade. Changes of grade were eased off by ordinary vertical parabolic curves.—C. A. JORSS

Concrete roads, past, present and future. S. H. WALKER. *Structural Eng.* (England), Feb., 1931, V. 9, No. 2, p. 55-64.—In a discussion of progress in the art of road building the disadvantages of joints is pointed out. The Illinois Bates Section is shown with excerpts from various reports presented at Sixth International Road Congress. Since British roads are subjected to extremely heavy traffic, with axle loads up to 28 tons and with steel or hard rubber tires, the importance of smooth joints is far greater in Great Britain than in America. A patented interlocked joint was developed to improve joint efficiency. An apparently crackless concrete road, free from opening and closing joints, has been built from a design of C. P. Courtenay, Borough Engineer, Greenwich. Details are given for this road which consists of a reinforced grooved concrete base topped by a 9-in. thick plain concrete road crust. Grooves which key road crust to base cause invisible closely spaced cracks. Preparation of the sub-grade varies with the soil conditions. Mr. Courtenay's design has been patented as "Anchorete" concrete road. Further application of "Anchorete" plan has been made to resurfacing of old roads.—V. P. JENSEN

The bureau of public roads. THOMAS H. MACDONALD. *Civil Engineering*, March, 1931, V. 1, No. 6, p. 494-496.—Article contains an interesting description of studies of cement concrete made by the Bureau of Public Roads, including measurements of expansion and contraction of concrete due to temperature and moisture change; determinations of effect of alternate freezing and thawing, both during and subsequent to setting period; determinations of effect of time of mixing in full-size paving mixers on strength and uniformity of product; the effect of alkali salts in soil and water on concrete; and means of protecting concrete against alkali attack by bituminous paint coats. Other useful studies deal with effect of kind and proportion of coarse aggregate upon strength and density of resulting concrete. Nearly all concrete pavement curing methods thus far proposed have been tested in an investigation carried out on a section of Tennessee highway 15 miles long. One-half of pavement throughout entire length of road was cured with wet earth and character and behavior of concrete thus treated have been taken as standard of comparison by which relative effects of other curing methods used on the other half of pavement have been determined. In an effort to rationalize design of concrete road slabs, the bureau has experimentally evaluated practically every factor involved except important one of subgrade support. Experiments have yielded all necessary data with reference to contraction, expansion, and warping of slab under various conditions of temperature and moisture. Coefficients of friction between slab and various subgrades have been determined, and distribution of pressure to subgrade from loads applied at various points on pavement measured by soil pressure cells. Related effects upon pavement stresses of joint spacing, subgrade friction, and kind and position of steel reinforcing have been fully explored; and, finally, distribution of stress induced in slab by applications of static loads and impact forces has been studies to a definite conclusion, qualified only by undetermined influence of subgrade variation.—D. E. LARSON

ARCHITECTURAL DESIGN

Build business district of concrete in residential suburb. *Concrete*, March, 1931, V. 38, No. 3, p. 16-17.—Monolithic concrete, concrete masonry and stucoo with cast stone trim are being used in construction of Texas suburban commercial center, in conformity with architecture of Spanish village. Arched entrances and stone doors are reproduced in cast stone with travertine finish. All stone is dry tamped. Finish is obtained by sprinkling rock salt into molds before facing is placed and tamped. During curing salt is dissolved by frequent washing. Holes remaining provide rugged, porous finish. Pleasing color obtained by using white portland cement with coarse, whitish Texas stone and river sand, proportioned 1:1½:1½.—C. BACHMANN

Form details and practice developed for architectural concrete. *Concrete*, March, 1931, V. 38, No. 3, p. 39-42.—Clear cut lumber and fiber board form lining were used in Pacific Coast buildings. Lining was used on all form work intended for flat wall faces. Corners were rubbed down with sandpaper and surface coated or greased with form oil and wiped off. Vertical beveled strips used to obtain fluting were made from kiln-dried spruce, planed, and grain filled with lead and oil before being nailed to forms. Mixing proportions ranged from 1:2½:3½ to 1:2:3, with slump of 4 to 5 in., and 7 to 8 in. for architectural concrete. Horizontal straight lines were obtained at day's work plane by tacking dressed 2 by 2-in. horizontal strip within wall form, against outer face, and at level where concreting is to be stopped for day. Fresh concrete was then placed to a level about ½ in. above lower face of strip and sloped downward toward inner face of wall. About two hours later strip was removed and entire surface of concrete cleaned with stiff broom. Forms were removed six or seven days after concreting. Following removal, exposed surface were given wire brushing to remove fins and films. Waste molds were left in place until building was practically completed when decoration was cleaned with wire brushes and allowed to dry out until uniform in color, followed by fine dash of colored stucco or oil stain, for polychrome effects. Patching mortar proportions were same as for concrete.—C. BACHMANN

Technique and form in cast stone. E. HEMMINGER. *Beton u. Eisen* (Germany), Oct. 20, 1930, V. 29, Heft 20, p. 362-364.—Artificial stone with its manufacture based on wide experience and scientific investigation must be accepted as a satisfactory building material—technically and economically. A recent pamphlet, (*Der Betonwerkstein* by Bund der Deutschen Betonwerke E. V.), is referred to for detailed information on the properties and advantages of artificial stone. Adaptability of cast stone has made it especially suited to lines of modern architectural design. Effects obtained with various aggregates offer a wide range of possibilities in color schemes. Different surface treatments present many variations in appearance. Cast sculpture or cast ornaments may be employed to emphasize portions of a structure or to relieve an otherwise monotonous elevation. A comparatively large market is presented in the field of garden and cemetery architecture. Benches, springs, statues, arbors and monuments may be constructed of cast stone since the modern product has shown itself to be a durable weatherproof material. The time of cramped imitation of natural stone is past and the new material is developing a style and form of its own. Its nature makes it available for designs for which other building elements are unsuited. The latest use of cast stone which has been forced to overcome some resistance on the part of conservative authorities is in church architecture. The Frauenfrieden Church in Frankfurt, A. M., is one of the striking instances of the employment of cast tiles for exterior facing. Interior equipment such as altars, baptismal fonts, etc., may be designed very effectively in cast stone.—A. A. BRIELMAIER

Field Construction

Bridges

Ancient bridges and their preservation. Steven Norris. *Roads Rd. Constr.* (England), March 2, 1931, V. 19, No. 99, p. 79.—Various means of renovating and reconstructing ancient bridge into a condition of traffic efficiency were applied without detracting from the bridge's authenticity as an ancient monument. First method is that of lining voussoirs of arch and faces of the abutments with a strengthening shell either of reinforced concrete, concrete or masonry. New arch is formed below existing arch and the existing abutment thus stiffened, the new facing taking some of thrust. New footings for lining wall will probably be required but if not possible then corbels may be tied into the old abutment to take reactions. Finished lining may be stepped or splayed off 4 or 5 in. from the external face of bridge. The second method consists of removing road surface down to arches, repairing and rejointing them where required and packing concrete from haunches to crown level, and reinstating road surface. If this method raises crest of bridge inconveniently high, coping of parapets may be raised by inseting a course or two of well weathered masonry from old local walls, etc. Further stiffening of the arches below may be supplied by erecting two or three arch ribs in masonry, concrete or reinforced concrete, below the arches; the ribs being well keyed to the existing masonry. The third method consists of the demolition of one half of the bridge floor or brick arches at a time, without in any way disturbing the external faces or parapets. The arches are then rebuilt entirely in any form desired. The abutments and piers should be thoroughly overhauled, repaired and grouted where required before erecting new arch centering. Arched slabs between piers and abutments, or springing from new lintels laid on the pier walls, or reinforced concrete girders at 2 or 3 ft. centres, supporting flat precast slabs may be employed. The fourth method is for use when the bridge is too frail to act in any way towards supporting modern traffic. The old bridge is retained merely as a shell to the new and entirely self-supporting structure built above the old arches. A new reinforced concrete single span arch is built and supported on new abutments behind old abutments. Old bridge may be employed to support weight of the centering. In fifth method when the old bridge only needs considerable stiffening, two or three narrow trenches are cut through the floor of the bridge. Centers are erected and the new separate single span arch ribs are constructed springing from the old abutments or new ones behind. —John E. Adams

Buildings

Experiences with aerocret-gas-concrete. Werner. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 63-4.—Experiences with a light concrete during construction of large dwelling house, are given. New material shows great advantage over ordinary concrete for certain purposes. Insulating properties for heat and sound are exceptionally good. Handling of large size stones is very easy. Plaster adheres very well to porous material.—A. E. Beitlich

Well foundations for construction of several buildings of German Museum in Munich (Germany). Karl Baessler. *Report 33rd main meeting German Concrete Association,* March 17, 1930, p. 409-30.—Design and method of construction of foundations for 2 large reinforced concrete buildings embodied new interesting features. Location of structures is on island in river Isar where underground conditions are extremely bad. Several layers of marl, sand and gravel, with 12-ft. loose materials, are on top of sound blue clay. Drillings were made to depths of 82 ft. to investigate bearing capacity of underground. Great variations in this direction led to construction of concrete

piers in open wells. Cylindrical piers are from 3.28 to 4.10 ft. in diameter and 32.8 to 39.7 ft. deep, belled out at base to 9.8 ft. in diameter. Twelve rotary tower drills traveling on top of wells were in operation. Steel tubes were from 4.9 to 6.6 ft. long and thickness of walls was 0.4 in. Loose materials were removed by streams of water, while grabbucket dredge was used for harder strata. Bell shaped excavations for footings were made by hand with compressed air shovel. Concreting was by continuous shoveling of plastic mixture until ground water level was reached. After pulling steel tubes remainder of concrete was placed thus preventing washing out of cement by ground water. Tops of 500 piers were connected with horizontal reinforced concrete girders which support basement walls. Only 2 piers had to be replaced.—A. E. BEITLICH

Winter concreting with use of gas burners. V. SMITKA. *Beton u. Eisen* (Germany), Nov. 20, 1930, V. 29, Heft 22, p. 404-406.—Construction of office building for "Berg und Huettengesellschaft" in Prague continued through unusually cold winter of 1928. Building has a ground area of 26,900 sq. ft. with three sub-basements and required an excavation varying from 33 ft. to 53 ft. below street grade. Two measures were adopted to insure satisfactory concrete: protection of site with temporary wooden enclosures, and heating of aggregate. Temperature in these temporary sheds was maintained at about + 36° F. by means of stoves, while the outside temperature occasionally dropped to — 15° F. The aggregate was placed in the mixer in frozen condition. A six nozzled, fork-like fitting was connected to the city gas line and the flames directed into the upper part of rotating mixer drum. No cement or water was added until the aggregate had reached a temperature of 98° F. to 107° F. A curve was made giving the time of heating required for aggregate varying from + 14° F. to + 86° F. in temperature on arrival at the mixer. The curve is almost a straight line and calls for a heating period of zero minutes for aggregate at 86° F. and 5½ minutes for aggregate at 14° F. When the aggregate had been heated, flame was shut off and unheated water and cement added. Total time in machine could have been reduced by adding cement to frozen aggregate and allowing mixing to proceed simultaneously with thawing. Increased production could be obtained by using two mixers, one being employed only for heating purposes. Prof. J. Klokner made a study of the effect of the temperature of mix at pouring, on the compressive strengths of test cubes and found that a 41° F. mix developed 8-day strength of 910 lb. per sq. in. and a 68° F. mix 1710 lb. per sq. in. It is indicated, however, that this difference in strength decreases with time. Method of heating aggregate proved very satisfactory and has great advantage of permitting concreting to begin without delay caused by elaborate preliminary work. It is desirable to heat aggregate to highest possible temperature and to lower temperature of temporary enclosures accordingly, within reasonable limits, since the first procedure is simple and cheap while the second is difficult and expensive.—A. A. BRIELMAIER

DAMS

Foundation procedure at Owyhee dam. *Eng. News Record*, Jan. 29, 1931, V. 106, No. 5, p. 178.—Foundation problems, complicated by necessity of excavating and concreting a fault zone 190 ft. below stream bed, have been solved at 530-ft. arched-gravity dam being built for the Owyhee project in eastern Oregon, and concrete placing on the main structure is well started.

Completion of the removal of the 38,000 cu. yd. of material from the crevice in the fault zone permitted concreting operations on a full scale, and about 1,000 cu. yd. per shift are being placed in the structure from an 8-cu. yd. bucket handled by overhead cableway. In May, 1930, the 250-ft. open cut 50 ft. deep representing the length of the fault zone lying under the dam was filled with concrete. Five 12 by 12-ft. openings were left to permit excavation of the faulted material below. As excavation was completed in various section along the bottom of crevice, the timbering was removed and space filled with concrete. The granite aggregate is shipped 25 miles to washing, screening, and mixing plant, located about ¼ mile from the dam. The entire plant is designed to produce 1,000 cu. yd. in 8 hr. Proportioning the mix has as its objective production of a finished concrete, which is an economic balance between the qualities of strength, impermeability, and durability, with due regard for desirability of using all coarse aggregate brought to the site. Use of 1 bbl. of cement per cu. yd. gives a mix varying from 1:2.7:6.45 to 1:2.5:6.65, and a water-cement ratio of 0.9. The time of mixing is 1½ min. The 28-day strength averages 3,500 lb. per sq. in. Concrete pours are in 4-ft. lifts between radial construction joints. A period of 72 hr. is required between pours on the same section. Bond is insured by washing and cleaning the surface between pours. Provision is made for grouting the construction joints later under a pressure of 100 lb. per sq. in.—GLENN MURPHY

The Chute a Caron hydro-electric development. JAMES W. RICKEY. *Proc. Eng. Soc. Western Pennsylvania*, Jan., 1931, V. 47, No. 1, 43 p.—Details of power developments in Province of Quebec with description of drainage basin are given. Methods for concrete construction have been very completely described by I. E. Burks (cf. JOURNAL of the Am. Con. Inst., Feb., 1930, *Proceedings*, V. 26, p. 315). Of outstanding interest was use of precast obelisk of heavy reinforced concrete for diverting river. While work was going on a large reinforced concrete mass was built on the mid-channel island. Special provisions were made in its pedestal to allow blasting away one of supports to cause obelisk to tip into and block the main channel, thus diverting entire flow up to 50,000 sec. ft. into completed diversion channel and thus permitting construction to proceed on main dam in old river bed. The problem included many unknown factors, such as best way to start obelisk falling, effect of impact against surface of water, possible destruction when obelisk landed on river bed, etc. Extensive mathematical analyses were first made and a model built in hydraulic laboratory of Carnegie Institute of Technology on scale of 1 to 50 to represent section of Saguenay River, diversion channel and obelisk. By means of special recording devices, all mathematical analyses were checked and effect of water action in deflecting and cushioning obelisk were determined in the laboratory. Work done in laboratory was repeated in actual construction and data are given to show that prediction in laboratory was fulfilled when obelisk was upset into river so closely that the final resting place was within ¼ in. of pre-determined location.—P. J. FREEMAN

Zschopau dam near Kriebstein (Germany), a cast concrete job. SUTTER. *Report 33rd main meeting German Concrete Association*, March 17, 1930, p. 467-78.—Zschopau dam, completed in 1929, is concrete gravity dam with total height of 108.3 ft. It is arched on a 738 ft. radius. Crest is 787.4 ft. long and 13.1 ft. wide; greatest width at base is 72. ft. Spillway is arranged in two sections, each having 4 openings 22.9 ft. wide and 13.1 ft. high. All are provided with gates operated from top of dam. At base of dam water passes through three 8.5-ft. pipes with gates capable of discharging about 400 cu. yd. of water per second. Three turbines with an efficiency of 80.5 per cent produce about 8000 h. p. Expansion joints are provided at 65.6 and 82.0 ft. intervals. Copper sheet and asphalt packing were used to make them watertight. Drainage system consists of vertical drains spaced at 6.6 ft. intervals,

which are connected with horizontal drain tile. Concrete was made of mixture of 440-lb. portland cement and 165-lb. trass, special consideration being given to proper gradation of aggregates. Their composition was: 15 per cent sand (0-0.08 in.), 15 per cent sand (0-0.28 in.), 40 per cent gravel (0.28-1.2 in.) and 30 per cent broken stone (1.2-2.4 in.). Central concrete mixing plant was built on left side of river and aerial cableway of 1 mile transported structural materials to construction site. Four 1-yd. mixers discharged into buckets which delivered concrete to 4 distribution towers. (cf. Kirsten, *Bautechnik* (Germany), March-April, 1930, V. 8, p. 149, 233, 247.)—A. E. BEITLICH

MISCELLANEOUS

New German specifications for reinforced concrete. *Zement* (Germany), Jan. 22, 1931, V. 20, No. 4, p. 84-6.—Changes and improvements in new tentative German specifications for construction of reinforced concrete structures especially emphasize improved structural materials and new experiences in field of concrete composition and working.—A. E. BEITLICH

Precast units in slab construction. R. RALL. *Beton u. Eisen* (Germany), Oct. 20, 1930, V. 29, Heft 20, p. 370-373.—A review of precast slabs, beams and hollow tiles used in Germany today gives details of manufacture for various types. Reinforced roof panel of "asbestos-concrete" is one of the new developments. This panel, either flat or corrugated, is used on spans of about 4 ft. Because of the weight of ordinary concrete, panels are usually precast of light weight concrete and used only for roofs. Types cited are reinforced in one direction and vary in thickness from 2½ to 5 in., with spans up to about 8 ft. Various profiles are in use for precast beams. These are either placed side by side to form a slab, or are spaced up to 2½ ft. apart and slab units placed or poured between them. These beams are available for spans up to 20 and 25 ft. The Visintini truss is one of the best known beams. Several tiles for one-way and two-way slabs are shown. Some standardization of practice in span lengths and concentration on certain types are necessary for further development of this field of precast products.—A. A. BRIELMAIER

Modern construction engines. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 64.—New engines of great efficiency which are capable of handling very large quantities of materials were used for construction of large channel to river Rhine between Basel (Switzerland) and Strassburg (France). Dams are about 150 ft. wide and are built with modern elevating graders which discharge materials directly upon embankment. Areas ranging from 1,800 to 2,400 sq. yds. can be planed in 8 days. Concrete mixer and distribution system travels on same tracks and places 314 to 392 cu. yd. of concrete in 8 hr. Reinforcement is placed by same engine.—A. E. BEITLICH

An overturned 19,000-ton caisson successfully salvaged. *Eng. News Record*, Feb. 12, 1931, V. 106, No. 7.—During the construction of the piers for Mid-Hudson Bridge at Poughkeepsie, N. Y., one of the caissons tilted to 42½ deg. with the horizontal, necessitating considerable amount of labor in righting it. Each of two caissons, the largest on record, consisted of a concrete-filled steel cutting edge and truss system 60 by 136 ft. and 20 ft. deep with semicircular ends. The lower steel sections were fabricated and towed to the site, where they were filled with concrete. During filling and sinking of east caisson, the weakened clay walls suddenly gave way causing the caisson to lean and settle. Steps were immediately taken to prevent further movement by anchoring it to tugs, and by dumping gravel on the weakened clay bank. Caisson was finally righted by excavating material under high edge and applying a pull of 1,500 tons to top edge.—GLENN MURPHY

Concrete plant in Boston designed to eliminate production delays. W. E. TRAUFFER. *Pit and Quarry*, Feb. 11, 1931, V. 21, No. 10, p. 55-57.—Forsyth Street plant of Boston Transit Mixers, Inc., Boston, Mass., built entirely of concrete and steel requires only six men for operation. The com-

pany has another concrete plant at Roslindale, with capacity of 55 cu. yd. per hr. It began operation with a fleet of 10 transit mixers. When Forsyth plant went into operation, 20 of same trucks were added to fleet to serve both plants. Aggregates at new plant are discharged into steel hopper and belt-conveyed to three compartments of a 166-cu. yd. steel bin. Aggregates are conveyed to top of plant where a swivel chute deposits them in four of five compartments concrete bin; the fifth compartment of 250 bbl. capacity, is for cement. Aggregates are sand, two grades of gravel, and one grade of crushed stone. Bulk cement is unloaded from cars and pumped by pneumatic system to two concrete storage silos, from which it is moved, as required, to the 250-bbl. cement compartment by same 5-in. pump. Aggregates are fed through radial gates and cement is fed through a rotary valve into weigh hoppers. Each hopper has a scale with a weightometer attachment. Contents of the two weigh hoppers are discharged to charging hopper which, in turn, discharges mix dry into truck. Water is fed simultaneously to tank on truck. Deliveries are usually within a radius of five miles. Distances of 20 miles are not unusual. Most of market for concrete is for laying sidewalks and highways.—A. J. HOSKIN

Construction of the North Lock in Bremerhaven (Germany). A. AGATZ. *Report 33rd. main meeting German Concrete Association*, March 17, 1930, p. 324-88.—Author gives extensive description of enlargements and new constructions of North Lock. Entire construction program covers: (1) Outer harbor, 1148.3 ft. long, 393.7 ft. wide at harbor entrance and 262.5 ft. wide at lock entrance; depth of water along breakwater is 52.5 ft. (2) Lock, 1220.5 ft. long and 196.8 ft. wide with 47.6 ft. of water and 147.6 ft. wide passage opening. (3) Turning basin, 1312.3 ft. long and 787.4 ft. wide; depth of water is 42.7 ft. (4) Connecting canal, which is 147.6 ft. wide. (5) Swing-bridge, distance between rest piers is 367.2 ft., main girders are placed 53.1 ft. apart and carry two railroad tracks for freight and passenger service, one wide roadway and a 9.2-ft. wide cantilevered sidewalk. (6) Enlargement of inner harbor to a length of 984.3 ft. and a depth of 42.7 ft. (7) Extension of a dock from 879.3 ft. to 1099.1 ft. Work was started in 1927 and will probably be finished in 1931. After its completion, this harbor will be one of greatest European ports and capable of meeting greatest traffic and largest ships. Over 400 holes were drilled to depths of 164 ft. to study underground conditions. Results of this investigation are given in details. Axis of new outer harbor structure is about 154.2 ft. farther west than axis of old harbor. Construction of break-water and harbor walls was carried out in great number of divisions for which 20 different cross-sections were calculated according to variations of underground. Concrete walls rest on wooden pile foundations, which were more resistant than concrete piles in this particular kind of sea water. About 600-lbs. blast furnace slag cement and 100-lbs. trass were used for 35.3 cu. ft. of concrete. Top of walls was provided with 20-in. wide strip of basalt slabs roughness of which facilitates walking. Steel sheet pilings of Larrsen type were used for wall construction. Inner and outer head of lock are of similar design and were built under considerable difficulties due to bad underground. Construction was of reinforced concrete after lowering groundwater level. Bottom slab is 21.3 ft. thick. Water pipes are shaped like trumpets in order to furnish favorable flow conditions. Lock can be filled in 18 to 29 minutes. Shape and reinforcing of heads are illustrated in several drawings. Smallest width is 32.8 ft. greatest 39.7 ft. and height is 65.6 ft. Gates are of sliding type, 27.9 ft. wide, 62.3 ft. high and 152.9 ft. long. Steel structure of swing-bridge rests on heavy reinforced concrete foundation constructed between steel sheet pilings on sound underground. Two end piers rest on wooden pile foundations. Three engine houses were erected for operation of gates and swing bridge. It is also necessary to build a 220 ft. extension to old dock, which is now 879.3 ft. long. Ten different cross-sections are calculated and discussed. New dock will be able to hold ships with capacities of 80,000 tons. Last part of article gives data about amount of consumed structural materials,

volume of excavations, arrangement of site of construction, progress of construction program and general information. (cf. *Bautechnik* (Germany), June 6, 1930, V. 8, No. 25.)—A. E. BEITLICH

Precast concrete balconies. *Conc. Building Conc. Products* (England), Dec., 1930, V. 5, No. 12, p. 162.—An illustration is given of a new type of precast concrete balcony for use in cinemas and theatres. The treads and risers are precast in one unit with continuous reinforcement, and at the back of tread on underside, is a notch to fit rolled steel joist supporting the stepping. On top side is another notch to receive the riser above. The risers are 2½ in. and the tread 3½ in. thick. The edges are formed to make joggled joints, and strips of wood are cast in the treads for nailing floor boards, etc.—JOHN E. ADAMS

Omaha firm sells both central-mixed and mixed-in-transit concrete. *Pit and Quarry,* Nov. 19, 1930, V. 21, No. 4, p. 40-43.—Ready Mixed Concrete Co., Omaha, Neb., has new central plant to produce concrete by two methods. Aggregates and cement flow by gravity from respective hoppers into weighing batchers and then to truck-loading chute. The aggregates hopper has two compartments of combined capacity of 75 cu. yd. Cement hopper holds 20 tons. Cement's flow to batcher is controlled by a dumping gate. A timing dial on aggregates scale indicates approach of correct weight. Batch hopper has a capacity of 10 tons. The cement batcher has a capacity of 2,500 lb. and has a similar scale. A small 110-volt vibrator is mounted on cement-discharge to prevent cement from sticking. Water is measured volumetrically from a square steel tank by a short length of pipe inside the tank capable of being raised or lowered to vary the quantity of water withdrawn in 5-gal. units, up to 120 gal. "Sand-gravel" in this field means mixture all of which will pass 1-in. mesh, and 50 per cent of which will not pass a No. 10 screen. This aggregate is received in carloads at plant, and is handled directly from storage into hoppers. Cement, purchased in bulk, unloaded from cars by power shovel into small receiving hopper at ground level. Thence it passes to the cement hopper or to storage. As needed stored cement is fed again to the bucket elevator. Delivery of concrete is made free of charge within Omaha city limits, with a charge of 25¢ per cu. yd. mi. elsewhere. Four mixes are standardized and sold under guaranteed strengths varying from 2,000 to 3,600 lb. per sq. in. An electric system of communication enables the shipping clerk in his office to flash a series of numerals at the batching operator's station to indicate the quantity of an order and the mix.—A. J. HOSKIN

ROADS AND PAVEMENTS

Rigid inspection produces better pavements. *Eng. News Record,* Jan. 8, 1931, V. 105, No. 2, p. 77.—Supervision of contract paving in Detroit by city engineer's office during last 6½ years has increased the 28-day strength of drilled cores by 25 per cent. By making richer mix, eliminating soft, dusty limestone aggregate, and increasing the time of mixing, the average 28-day compressive strength of drilled cores has been increased to more than 3200 lb. per sq. in.—GLENN MURPHY

Truck operation and production in concrete paving work. A. P. ANDERSON. *Public Roads*, Feb., 1931.—Analyses of time losses in production suffered by reason of either an insufficient supply or faulty operation of hauling equipment used in concrete road construction, and results of studies on 100 concrete paving jobs show an average time loss of 17 per cent due to these causes. These time losses may be considerably reduced by applying a number of governing principles which are discussed in detail in the report indicating importance of properly designing the material yard layout and shows the amount of loss due to faulty layout. Tables and charts are included from which the proper number of trucks to use under any given set of conditions may be computed. Contract hauling is not in general profitable to contractor, because conditions are often such that greatest profit to hauling contractor accrues at rather low rates of production.—F. H. JACKSON

A study of methods of curing concrete pavements. F. H. JACKSON AND E. W. BAUMAN. *Public Roads*, Jan., 1931.—In field investigation in Tennessee conducted jointly by the Bureau of Public Roads and Tennessee Department of Highways, experiments were conducted on a concrete pavement approximately 15 miles long, pavement on one side of longitudinal joint being cured in 1000-ft. sections with the various curing methods under consideration while concrete on other side of joint was cured with earth and water in the conventional manner for comparison purposes. The following methods of curing were investigated: Wet burlap applied for 12 to 96 hrs.; no cure; Sisalkraft paper applied for 24 hrs.; sodium silicate—earth subgrade, tar paper on subgrade; calcium chloride, surface application—earth subgrade, tar paper on subgrade; Hunt process—earth subgrade, tar paper on subgrade; Barber asphalt emulsion (curcrete)—earth subgrade, tar paper on subgrade; Headley asphalt emulsion—earth subgrade, tar paper on subgrade; Tarvia K. P.—earth subgrade, tar paper on subgrade; Tarvia B—earth subgrade, tar paper on subgrade; poor earth cure; ponding; calcium chloride admixture—earth subgrade, tar paper on subgrade. Total length of pavement tested was 74,148 ft. A large number of concrete beams and cylinders were made and tested and results analyzed in detail. In addition results of two detailed crack surveys of pavement are given. Conclusions as to relative efficiency of various curing methods are based on consideration of strength developed by concrete beams cast alongside pavement sections and cured in same manner, concrete cores drilled from the pavements and the results of crack surveys. Efficiency of curing method as applied to each section was determined by comparing results for that particular section with results obtained for the standard water cure on the same section. In this way accidental variables such as subgrade conditions, etc., were largely eliminated. It is believed that results of this investigation justify following comments relative to merits of various curing methods as compared with standard method of curing with earth and water, under conditions prevailing during progress of these tests: 1. *Burlap curing*—Method of cure involving application of wet burlap for periods varying from 24 to 96 hr. without further curing compares quite favorably with standard method. No final conclusions can be drawn until additional tests under more severe weather conditions are made. 2. *Sisalkraft paper*—Application of Sisalkraft paper for periods of 24 to 48 hr. without further curing is a reasonably satisfactory method of cure compared with standard method. 3. *Poor earth cure*—It is not necessary to keep earth saturated with water for entire 10-day curing period. 4. *Sodium silicate*—This method of cure gives results somewhat less satisfactory than those given by standard method. 5. *Calcium chloride, surface application*—Results very nearly as satisfactory as standard method. 6. *Calcium chloride admixture*—Sections on which admixture was used are too short to warrant any conclusion as to merit of this method. 7. *Bituminous materials*—Curing with bituminous materials, as used in these tests, is unsatisfactory, because of the marked evidence of increased transverse cracking. 8. *Tar paper on subgrade*—Nothing is gained by its use.—F. H. JACKSON

SHOP MANUFACTURE

To prevent cracks in masonry walls. W. D. M. ALLAN. *Concrete Products*, Jan., 1931, V. 40, No. 1, p. 27-29.—This article was prepared to provide products manufacturers with information to refute the claims of competing materials that cracks necessarily occur in concrete masonry. A number of drawings illustrate the best methods of preventing cracks.—E. S. HANSON

Long established pipe plant adopts machine manufacture. *Concrete Products*, Feb., 1931, V. 49, No. 2, p. 20-23.—The Core Joint Concrete Pipe Co., at Irvington, N. J., which has been manufacturing hand made pipe for a number of years, has recently added a department for making pipe by machine, the process being of particular interest in that it provides for lining the pipe by machine at the same time as it is manufactured. A mix is applied hot and automatically trowelled into the wall of the freshly made pipe. This liner mix is composed principally of specially graded sand, slate flour and ordinary paving asphalt.—E. S. HANSON

Das betonwerkstein (cast stone) TAMMS. *Betonwerk* (Germany), Dec. 21, 1930, V. 18, No. 51, p. 715.—In present methods of making cast stone discussed, aggregates are selected for their durability and appearance, carefully graded and recombined. The surface of the cast product is cut to resemble cut stone. It is suggested that this method may not be ideal but a surface which reflects the mold in which it is cast may produce a product more in keeping with the nature of concrete. Under certain conditions such as with the use of a hard aggregate the employment of the sand blast may produce interesting surfaces, also the Contex method is suggested in that individual grains or aggregates are fully exposed. Examples in France and America are cited, especially, several examples of work done by Frank Lloyd Wright in California.—H. FRAUENFELDER

A new column fireproofing unit. ROBT. H. MOORE. *Concrete Products*, Jan., 1931, V. 40, No. 1, p. 22-23.—Segmental units for fireproofing steel columns were developed by the Detroit Cinder Block & Tile Co., Detroit, Mich., for use on one particular job but have proven so successful as to be added to the regular line of products. These are made in circular and octagonal shapes, the circular units three to a circle and the octagonal two to a circle. The units are 2 in. thick and 8 in. high, with the length depending on the size of the column to be fireproofed.—E. S. HANSON

Profitable manufacture of concrete building units. FRED A. SAGER. *Concrete*, March, 1931, V. 38, No. 3, p. 27-29.—With approximate idea of space requirements of each part of manufacturing process, preliminary block plan may be drawn up. Use of outline sketches of various parts of plant, drawn to same scale as property site and cut out on separate pieces of paper, to be arranged in various combinations so that advantages of different locations may be studied, is suggested. Two fundamental characteristics of layout should be arrangement for future extension, and one-direction flow lines for material through the plant. Equipment space includes area for elevator and crusher adjacent to cinder storage and for boiler near coal storage, all located near railroad siding. Manufacturing plant includes two standard block machines, brick machine, hand-operated machine, mixer, motors, storage for pallets, etc. Advantageous stock-piling and area required are determined. Diagram illustrates provisions for materials, equipment and traffic.—C. BACHMANN

New product gave us our best year. C. V. BERRY. *Concrete Products*, Feb., 1931, V. 49, No. 2, p. 17-19.—Addition of manufacture of concrete floor

joists gave a products manufacturer in Kalamazoo, Mich., a successful business during 1930 in spite of unfavorable conditions. These floor joists are shaped somewhat like a steel I-beam, having top and bottom flanges 3 in. wide and a web thickness of 1¼ in. The section is made 8 or 10 in. high and up to 20 ft. in length. Adequate tensile and sheer reinforcement is provided in a welded unit to resist externally imposed loads with an ample factor of safety. Sand and Haydite are used as aggregates, the mixture being proportioned as 1 part cement, 2 sand, 2 fine Haydite and 4 coarse Haydite. Special equipment has been developed for manufacturing these floor joists approximating somewhat the method of rolling steel rails in a steel mill—E. S. HANSON

Concrete sign posts. *Conc. Bldg. Conc. Prod.* (England), Feb., 1931, V. 6, No. 2, p. 18.—Precast concrete sign post, made with colored cements, results in saving of maintenance costs. Posts could be in white cement, and the arms white with black letters or vice versa. Cap could be of any standard design. Letters are cast separately and attached to arms later, arms being left with a rough face. Rough surface may be formed by fixing ½-in. mesh wire netting to the panel which forms sinking for letters, so when the side forms are released netting comes away also, leaving a surface with a good key. Letters should be ⅝ in. in thickness with ⅜ in. embedded in concrete, and composed of 1:2 mix with clean sharp sand. Fixing is done with a slight skimming of neat cement and filling made with 1:3 mix in the desired color. The suggested mixes are as follows: 1:1½:3 (½ in. to ⅛-in. ballast with clean sand or stone dust) for posts; 1:1½:3 (⅜ in. to ⅛ in. as above) for arms and caps. Reinforcement for post should be four ½-in. rods with ⅛-in. wire ties at 12-in. centres, and with 1-in. cover. For arms two ⅜-in. rods tied at 6-in. centres are recommended.—JOHN E. ADAMS

Concrete block tunnel lining. ERNEST H. ROWE. *Concrete Products*, Jan., 1931, V. 49, No. 1, p. 12-14.—Manufacture and installation of segmental concrete block for lining one of extensions of New York's system of rapid transit subways include interesting details. The bid of the successful contractor was $387.00 per lineal ft. of lining as against $524.00 per lineal ft. for cast iron lining. In addition to the money saving the concrete block tunnels were completed in much less time than cast iron tunnels. Ten blocks per ring were specified, outside diameter of ring to be 3 ft. greater than inner diameter which was 16 ft. 9 in. Each block was 5 ft. 2⅞ in. on the arc of the concave face with a width of 2 ft. 6 in. and a radial thickness of 18 in. Forms for each block were set up on a car and the cars handled in trains of 30 under mixer. Each block was reinforced with two mats of five ⅜-in. rods. Interlocking of the rings was provided for by two projections, on one side, and corresponding depression on opposite side.—E. S. HANSON

Reinforced concrete window frames. W. CHRISTEN. *Beton u. Eisen* (Germany), Oct. 20, 1930, V. 29, Heft 20, p. 375-377.—The speed with which modern structures are being erected has created a demand for factory-built and standarized building units. These units lead to an improvement of the construction and to lower costs. Window openings had formerly been built up on the job of separate precast units or of brick. Necessity of economizing on labor has led to quantity production of reinforced concrete window frames—a product which has come into greater use in the last few years. Advantages of this ready-built unit are: more effective and exact construction; lighter weight (a frame unit with 4 ft. 7 in. by 3 ft. 9 in. opening weights 310 lb. as against 1210 lb. formerly necessary); easier erection. In order to further the use of this type of unit it is necessary to standardize openings and frame sections. Experience has shown that less than 20 pieces of one type cannot be manufactured at a price low enough to compete with the older methods. (Abstractor's note: In accordance with German practice these frames are all for casement windows.)—A. A. BRIELMAIER

Media plant pioneers in manufacture of light-walled units. J. J. BUZZELL. *Concrete*, March, 1931, V. 38, No. 3, p. 21-22.—Media Concrete Products Co., Inc., Media, Pa., has successfully developed light-weight building unit of improved design, using ordinary aggregates. In addition to old style standard sizes, units 7¾ by 7¾ by 15¾ in. and 7¾ by 11¾ by 15¾ in. have been adopted. Fifty per cent air space was found most satisfactory. Mortar bed of 1½ in. is provided due to sharp flare at top ledge. Units are manufactured in two classes. First employs combination of hard aggregates resulting in dense concrete, not nailable but intended for underground work. 7¾ by 7¾ by 15¾ in. size weighs 36 lbs., and 7¾ by 11¾ by 15¾ in. size weighs 45 lb. Other type of light-walled unit provides extreme light-weight and free nailability with slight crooking of nail. 7¾ by 7¾ by 15¾ in. size weighs 30 lb. and 7¾ by 11¾ by 15¾ in. size weighs 38 lb. Besser senior stripper and 25-ft. mixer, and one size plain pallets for all units are used. Air-tight steam enclosures at siding are provided for thawing out cars of freezing aggregates. Large block storage area is at car level adjacent to siding, so cars may be loaded by rolling units from stock-piles into cars. Overhead storage capacity is divided into nine separate, covered bins equipped with steam heating facilities. Mixer floor is directly beneath overhead bins, mixer hoppers are fed from any bin desired by 18-in. cross conveyor and machines are located directly under mixers on lower floor. Arrangement of racks around machines allows continuous machine operation, using electric industrial track.—C. BACHMANN

Some new prospects in the development of the concrete product industry. R. JECHT. *Beton u. Eisen* (Germany), Oct. 20, 1930, V. 29, Heft 20, p. 368-370.—The profitable manufacture of concrete units depends on two conditions; a large or steady demand for same product, need or economy of high-quality product for special purpose. The first condition has led to mass production of pipes, slabs, poles, etc. In some cases the same product satisfies both conditions. Class of units meeting second condition is not clearly defined. A high-quality product requires long experience, expensive experimental work and thoroughly trained workmen. Best results of progress made in concrete proportioning and treating can be realized only in permanent factory with experienced personnel. Progress in widening the field is marked by costly failures. Aim to manufacture units which will utilize, on the job, modern transportation and erection equipment is correct. Only in this manner can concrete products benefit, as steel has done, from progress made in erection equipment. A few examples follow: Highway viaduct in Klingenberg, Saxony, is built of A—frames with centrifugally-cast poles up to 56 ft. long. Frames are stiffened longitudinally by the deck and at about one third height by two horizontal members from frame to frame. The corners and connections were made secure after erection by pouring mortar in the joints or casting a concrete block around them. The form costs for pouring this job on the site would have been prohibitive. Units for poles and towers for pipe lines and high tension lines have come into use but face a very strong competitor in steel, due to the present low steel prices. In Italy where the position of steel is not so strong, these towers have been more widely used. Recently in the improvement of Konigsberg Sea canal 60 three-pile (centrif-cast) foundations were used for sea beacon bases. These piles are exposed to a strong ice pressure. Use of precast units, as wall panels, roof slabs, has proved economical for garages and other small jobs. In Germany the use of concrete water pipes is just becoming noticeable while in other countries much progress has already been made. Here again the centrifugally-cast product is in the lead.—A. A. BRIELMAIER

Technique and form in cast stone. (See ARCHITECTURAL DESIGN.)

Precast units in slab construction. (See FIELD CONSTRUCTION—Miscellaneous.)

Materials

Admixtures

Slaked lime as a means towards denser concrete. R. Grun. *Summary Reports First I. C. for C. and R. C.*—Relations between impermeability and strength of concrete: Against physical effects; against chemical action. The making of watertight concrete: Effect of lime upon: plasticity, tensile and compressive strength, compactedness, resistance to frost, resistance to chemical action.—La Technique des Travaux

Effect of several admixtures on portland cement. P. P. Budnikoff and M. I. Nekritsch. *Zement* (Germany), Feb. 26, 1931, V. 20, No. 9, p. 192-3.—In experiments at laboratory of technology of silicates in Charkow (Russia), cement was mixed with 1, 2, 5, 10 and 30 per cent of each of following materials: chalk, dolomite, dolomite burned at 750° F., dolomite burned at 1470° F., marl and marl burned at 1110° F. Admixtures were ground together with clinker in laboratory ball mill. Standard 1:3 mortar specimens were made for compressive and tensile strength tests and stored in water and artificially made sea water. Tensile strength of pure cement is in general slightly higher than that of cements with admixtures. Compressive strength is mostly improved by above materials. Admixtures increase density and adsorbing properties of mixtures. Additions of as much as 10 per cent do not affect value of cement. Most economic admixture is chalk. Large scale tests along same lines are in progress.—A. E. Beitlich

Aggregates

The composition, mixing, methods of application of concrete and reinforced concrete as used in the yards and the control of same. T. R. Grigson. *Summary Reports First I. C. for C. and R. C.*—The paper is divided into various headings which may be summarized as follows: Composition of concrete; cement, aggregates, proportioning, admixtures and fillers. Mixing concrete; methods of application.—La Technique des Travaux

The application of sieve analyses and Abrams' fineness modulus. A. Hummel. *Summary Reports First I. C. for C. and R. C.*—Influence of gauge of inert materials on strength of mortar and concrete has been zealously studied in laboratories during past 25 years. Results obtained have been correlated in ideal granimetric curves (Fuller, etc.) or rules for gauging. The value of these curves for scientific research and for laboratory practice is unquestionable, but for use on the works it is questioned. This paper indicates a more general method of estimating qualities of inert materials from grainmetric point of view.—La Technique des Travaux

Criticism of fineness modulus. A. Hummel. *Zement* (Germany), Feb. 5, 1931, V. 20, No. 6, p. 129-34.—Author discusses investigators' comments on his paper "The valuation of sieve analyses and the fineness modulus by Abrams" *Zement* (Germany), April 1930, V. 19, No. 15, p. 355-64; Journal A. C. I., June 1930, V. 1, No. 8, *Abstr.* p. 108. Too refined mathematical calculation can not be applied to this subject without making method valueless for practice. Advantages and disadvantages of method, especially its speed of calculation, are illustrated.—A. E. Beitlich

Ideal curve, fineness modulus and the new standard specifications. Kristen. *Zement* (Germany), April 16, 1931, V. 20, No. 16, p. 366-9.—A comparison is made of ideal curve, curve by Otzen and Abrams' fineness modulus. New text of German standard specifications for reinforced concrete is discussed. Best and most economic way to improve a material is to compare its sieve analysis with ideal curve (without cement). If it is necessary to add coarse materials, percentages of these additions can be found with fineness modulus by method of Hummel. Graphical method for plotting curves is explained, especially conversion of Tyler sieve openings into metric equivalents. —A. E. Beitlich

About mesh openings and particle sizes. JOHS. ANDERSEN. *Zement* (Germany), March 5, 12, 1931, V. 20, No. 10-11, p. 224-6, 242-5.—Study was undertaken to replace measurement of mesh openings in sieve analysis by determination of average diameter of particles which can just pass sieve when sieving process is completed. This fraction is called size separation (Kornscheide). Investigation covered (1) pure separation, (2) relation between average mesh opening and size separation of certain sieves, (3) demonstration of sieve analyses and (4) size separation of sieves with different materials. Fineness curves are much smoother than those based on mesh openings. Relation of size separation to mesh opening is about 0.81 in case of mostly spherical particles and slightly less for particles with sharp edges.—A. E. BEITLICH

Synthoporit—A new light-weight structural material. H. F. KRAUSE. *Zement* (Germany), April 16, 1931, V. 20, No. 16, p. 372-4.—A very porous material is prepared from a fusion of calcium silicate. Melt leaves furnace at 2730 to 2910° F. and is chilled by patented process. Cold slag is then broken and sieve separated into certain fractions. Material consists of about 20 per cent solids and 80 per cent voids. It floats on water even after 3 months. It is not affected by high temperatures and its strength is not materially decreased when used as concrete aggregate and exposed to high temperatures. Chemical composition is close to wollastonite, 47-49 per cent SiO_2, 2-4 per cent Al_2O_3, 0.2-0.5 per cent FeO and 43-45 per cent CaO. Sulphur is below 0.3 per cent. Specific gravity is 0.6. Voids are mostly closed and do not absorb much water. It is highly heat insulating. Greatest field of application is concrete. It is used for manufacture of slabs, light weight bricks, ceilings, encasings for steel structures and walls. Concrete with synthoporit as aggregate has very favorable strength properties.—A. E. BEITLICH

Gravel plant of unusual design. H. M. FITCH. *Rock Products*, March 14, 1931. V. 34, No. 6, p. 33.—Hillside Washed Sand and Gravel Co.'s plant at Muskego, Wis., has screening and washing machinery mounted on an octagonal tower. Walls, or fins, run out from each angle of tower making eight spaces. Conveyor for recovering materials is installed in one space leaving seven for storage. Boot of conveyor is in base of tower and chutes from all divisions lead to it. A hoist is moved on a circular track around the storage to handle a scraper bucket to pull material in and out of storage spaces.—EDMUND SHAW

Quarry practice at the operations of the John T. Dyer Quarry Co. *Rock Products*, Feb. 28, 1931, V. 34, No. 5, p. 47.—The John T. Dyer Quarry Co., which has three plants near Birdsboro, Penn., is developing blasting technique and solving the problem of making the fines into a commercial product. Coyote holes are used at the Monocacy Plant. They are driven from a tunnel about 100 ft. back of the face, this tunnel being connected to the surface by a vertical shaft. The face is 300 ft. high and two tunnels will break the rock in two benches. At the Clingan Quarry well drill holes are set 20 ft. apart with 35 ft. burden. The rock broken ranges from 6 to 7 tons per lb. of powder. Four ton auto car trucks haul the rock to the crusher. The main crusher of the Monocacy Plant (60 by 84 in.) was once the largest jaw crusher in the world. Drive for this is most unusual. Fines have been sold as fine aggregate and recently part of them have been ground very fine to be used in the recovery of fine coal.—EDMUND SHAW

Proposed method of test for soundness of fine and coarse aggregate by use of sodium sulphate. Appendix 2 to the fifth annual report of the engineering and research division of the National Sand and Gravel Association. *Nat. Sand Gravel Bul.*, Feb., 1931, V. 12, No. 2, p. 41-42.—A procedure to be followed in treating fine and coarse aggregates to determine their resistance to disintegration by a standard solution of sodium sulphate, and equipment to be used. The solution, prepared by dissolving sodium sulphate in water at about 86° F., is allowed to cool to 70° F. and stand at least 12 hr. before use. For fine aggregate samples a balance of not less than 1,000 grams, sensitive to at least 0.5 gram, is required. Fine aggregate

passing ⅜-in. sieve shall be of such size that approximately 500 grams is coarser than No. 50; that portion finer than No. 50 shall be discarded. Fractions retained between No. 50 and 30, 30 and 16, 16 and 8, 8 and 4, and coarser than No. 4 sieves shall be weighed and placed in separate containers. For coarse aggregate samples a balance of not less than 5,000 grams, sensitive to at least 1 gram, is required. Coarse aggregate shall consist of material from which sizes finer than No. 4 sieve have been removed. Pieces showing incipient fracture due to crushing shall be removed. Weight of sample shall depend on maximum size of aggregate. Fractions retained on ⅜, ¾ and 1½ in. (square openings) shall be weighed and placed in separate containers. Number of particles shall be counted in fraction coarser than ¾ in. Immersed samples shall be stored at 70° F. for a period of 18 hr., and dried in an oven (from 212 to 230° F.) to a constant weight (not less than 4 hr.) then allowed to cool to room temperature. Care must be exercised to avoid loss of aggregate particles or detritus coarser than 100 mesh. Alternate immersion and drying shall be repeated until five cycles (unless otherwise specified) are obtained. Fractions coarser than ¾ in. shall be examined qualitatively after each cycle and quantitatively after completion of test. Fractions finer than ¾ in. shall be examined quantitatively only and after completion of test.—P. McKim

Aggregates and the physical properties of concretes: their coefficient of elasticity and their resistance to compression, tension, flexure, shear and impact. R. Dutron. *Rev. materiaux construction trav. publics* (France), July, Aug., Sept., Oct., Nov., Dec., 1930, No. 250, p. 258-62; No. 251, p. 293-8; No. 252, p. 343-9; No. 253, p. 383-9; No. 254, p. 431-5; No. 255, p. 473-7.—The coarse aggregate was Rhine or Meuse pebbles, or crushed porphyry, slag or sandstone; fine aggregate was Rhine sand or finely crushed porphyry. Some experiments were made with fine slags also. The best compressive strengths were obtained with mixtures of sand and gravel, because of the better packing so that less water was required. Three gradings were used with three different amounts of cement at three different consistencies each. Two kinds of cement were used. The concrete made of river sand and gravel is stronger under compression than when made of crushed rock. Deformability of concrete is influenced by the grading of sand and by the ratio of fine to coarse. Tensile results generally reversed those of compression, porphyry giving better values than gravel and fine crushed rock better than sand. Ratio of tensile to compressive decreases parabolically with age and for crushed stones lies in the range 0.093 to 0.075, while with water worn aggregates, 0.070 to 0.052. The flexural strength equals 1.63 times tensile + 12.5 per cent. Shearing resistance was determined by making beams with an offset center and was found to be closely proportional to compressive strength. Resistance to impact was determined. Specimens of crushed aggregate withstood pounding better than water worn materials. Mixtures gave intermediate results.—F. O. Anderegg

Cement

The cause of the "sanding off" of high alumina cement. A. F. Roscher-Lund. *Zement* (Germany), Feb. 19, 1931, V. 20, No. 8, p. 164.—Softening and sanding off of layers of pats of certain high alumina cements is due to too rapid drying out of surface causing incomplete hydration of cement. Carbonation which has been found to take place in these layers is only of secondary nature and not directly responsible for sanding effect. Opinion of H. W. Gonell on this subject is discussed.—A. E. Beitlich

The cause of setting failures of high alumina cement. H. W. Gonell. *Zement* (Germany), Feb. 19, 1931, V. 20, No. 8, p. 164-8.—Contrary to findings by Roscher-Lund, (cf. *Zement* (Germany), Feb. 19, 1931, V. 20, No. 8, p. 164), carbon dioxide and not too rapid drying is cause of sanding off of high alumina cement test pats. Tests carried out in previous years were repeated. Specimens were stored in moist air, moist carbon dioxide atmos-

phere, moist oxygen and dry oxygen. Same results were obtained. Differences in findings are due to different lime contents of investigated cements. Drying out of surface layer is only of minor importance.—A. E. BEITLICH

Notes on the use of special cements on the Netherlands East Indies state railways. P. A. JELLEMA. *Summary Reports First I. C. for C. and R. C.*—Rapid hardening cements of French, German and British manufacture have been used and in no case were strengths claimed for them obtained. It was established that capacity for rapid hardening diminished with the lapse of time. Control tests indicate that for the present these special cements should, therefore, only be adopted with the greatest care. The reason why the special cements deteriorate in quality is not yet known.—LA TECHNIQUE DES TRAVAUX

Improvements increase output of Dewey cement plant at Davenport, Ia. *Pit and Quarry*, April 8, 1931, V. 22, No. 1, p. 49-55, 61.—Plant which has been using closed-circuit wet finish grinding for about one year, first went into operation in 1927 but numerous improvenents were made prior to 1930, such as development of a new quarry level and a new clay pit, addition of several locomotives, enlargement of the crushing plant, installation of equipment for sizing aggregate for commercial trade, a clay-wash mill, a third kiln and a cooler, a wasteheat boiler, 24 storage silos, and slurry filters.—A. J. HOSKIN

Determination of magnesium in portland cement and similar materials by the use of 8-hydroxyquinoline. J. C. REDMOND AND H. A. BRIGHT. *Bur. of Standards Journ. Research*, Jan. 1931, V. 6, No. 1, p. 113-20.—Procedure given for determination of magnesium in portland cement is accurate and much more rapid than standard phosphate method. Directions for preparation of solutions are given. Determination can be carried out in about 2 hrs.—A. E. BEITLICH

Contribution to the ball mill theory. W. BARTH. *Zement* (Germany), April 23, 1931, V. 20, No. 17, p. 390-1—Reply to article by Naske (cf. *Zement*) (Germany), Feb. 12, 1931, V. 20, No. 7, p. 148-9) in which author states that materials in ball mills are only crushed by impact and not also by attrition. He explains ways of particles in mill and theory by Fischer. Naske gives his final opinion which is contrary to conception of author.—A. E. BEITLICH

About the manufacture of fused cement. WALTER MARSCHNER. *Zement* (Germany), April 16, 1931, V. 20, No. 16, p. 362-3.—Improvement of electric furnace for manufacture of high alumina fused cement facilitates discharging of materials. Temperature of melt must be raised considerably at point of discharge. This can be done economically by adding about 20 per cent of raw mixture to melt at outlet of furnace. Exothermic reaction of chemical constituents in mix causes rise in temperature which is sufficiently high for discharge. German patent (P 58,489) has been applied for.—A. E. BEITLICH

The degree of lime saturation by Kuhl. M. SPINDEL. *Zement* (Germany), April 9, 1931, V. 20, No. 15, p. 338-40.—A contribution to the question of final form of degree of lime saturation derived by Hans Kühl and modified by Hess (cf. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 28-32; JOURNAL A. C. I., April, 1931, V. 2, No. 8, *Abstracts*, p. 214). Author demonstrates degree of lime saturation in his four-component parallelogram and suggests further changes of this modulus. Application in practice is discussed. Kühl, in addition to his previous paper (cf. *Zement* (Germany), Feb. 5, 1931, V. 20, No. 6, p. 123-5), criticizes efforts by Hess and Spindel to modify his formula and claims that "degree of lime saturation" is only to be used for his original modulus.—A. E. BEITLICH

The degree of lime saturation by Kuhl. M. SPINDEL. *Zement* (Germany), April 16, 1931, V. 20, No. 16, p. 360-2.—Continuation of polemic between Spindel and Kühl (cf. *Zement* (Germany), April 9, 1931, V. 20, No. 15, p. 338-40). Author claims that calculation of his formula and of Hess' number can be simplified greatly by mathematical manipulation. Kühl gives short

reply and states that practice must decide which method is most suitable for proportioning of raw materials.—A. E. BEITLICH

The formation of minerals from melts of kaolin-lime mixtures. I. WEYER. *Zement* (Germany), March 19, 1931, V. 20, No. 12, p. 264-5.—Mixtures of kaolin and lime were heated above sintering point and formation of minerals investigated to determine whether tricalcium silicate, already formed at this temperature, undergoes any changes. Five different brands of metakaolin and lime in proportions 1:8, 1:9, 1:10 and 1:12 were heated from 5 to 6 hr. at 2640° F. Mostly dicalcium silicate in beta form was observed in mixtures with less than 9 mols CaO. In mixtures with more than 9 mols CaO no dicalcium silicate was observed; all silica is combined as tricalcium silicate. —A. E. BEITLICH

The lime content of high alumina cement. HANS KUHL AND SETSUO IDETA. *Zement* (Germany), March 19, 1931, V. 20, No. 12, p. 261-4.—Efforts were made to determine most favorable lime content for high alumina cements by preparing several synthetic melts and studying their physical properties by small-piece testing method. Ratios of SiO_2:Al_2O_3:Fe_2O_3 were 15:35:10, 10:40:10 and 5:45:10. Lime contents in these cements ranged from high to low limit, calculated by means of formula for degree of lime saturation derived by Kuhl (cf. *Tonindustrie Zeitung* (Germany), March 20, 1930, V. 59, No. 23, p. 389-92). No direct relation was found between physical properties and chemical composition.—A. E. BEITLICH

Analysis of standard cements. H. BURCHARTZ. *Zement* (Germany), March 19-26, 1931, V. 20, No. 12-13, p. 258-60, 290-2.—A method has been worked out under supervision of Burchartz, Gruen, Guttmann, Haegermann and Luftschitz for analysis of portland cement, iron portland cement and blast furnace cement. Directions are given for preparation of samples, solutions and their standardization. Analysis includes determination of loss on ignition, silica, sesquioxides of iron and aluminum (special method is given for samples containing more than 1.5 per cent manganese), lime, magnesia, insoluble residue and sulfate.—A. E. BEITLICH

New ways in American cement manufacture. CARL NASKE. *Zement* (Germany), March 19-26, 1931, V. 20, No. 12-13, p. 266-8, 292-6.—Review of several articles gives special consideration to installations at American plants. Following points are considered as most essential: (1) Improving quality to effect that high early strength cement will be manufactured more than ordinary standard portland cement; (2) Investigation of wet process and increase of fineness of raw mixture and cement; (3) Lowering of production costs by slurry filtration; (4) Increased application of closed circuit grinding and use of vibrator screens and classifiers at raw feed end and air separators for cement; (5) Improved dust collecting systems and greatest attention to safety devices.—A. E. BEITLICH

Researches on the rotary kiln in cement manufacture.—Part 13. GEOFFREY MARTIN. *Rock Products*, Feb. 28, 1931, V. 34, No. 5, p. 72.—In calculation of theoretical flame temperature in a rotary kiln, it is assumed that 1-lb. coal gives gaseous mixture CO_2, 2.624 lb.; N_2, 7.669 lb.; H_2O, 0.448 lb.; excess air, 0.537 lb.; total, 11.278 lb. Air, including 5 per cent excess is put at 10.478 lb. and it is assumed to have a temperature of 60° F. Highest temperature that can be attained by combustion gases is about 4,000° F. To calculate the maximum temperature, the mean specific heats between 4,000 and 60° F. of the components of the combustion gas are taken from the author's tables of specific heats. (The water is supposed to be gasified at 60° F. and then heated to the maximum temperature T.) Then approximate flame temperature of T deg. F. is calculated and found to equal 3763° F. In this calculation assumption is made that specific heats of gases follow a straight line law between 60° and 4000° F. and also that mean specific heat between 60° and 4000° F is same as that between 60° and 3763° F. These

assumptions introduce two slight errors. Formula for calculating flame temperature is modified to: Total heat equals heat liberated by 1-lb. of coal plus heat brought into furnace by 10.478-lb. of air, equals 12,600 B.t.u. plus QT. A table is appended showing the B.t.u.'s required for preheating 10.478-lb. of air from 60° F to various temperatures. By substituting in the formula various values of QT in table, approximate flame temperatures corresponding to different temperatures of preheating are found. More exact determinations are then made. The difference between the B.t.u.'s absorbed in heating furnace gases from 60° F to 1481° F., and 12,600 B.t.u.'s is heat absorbed in heating gas from 1481° deg. F to its final temperature of T deg. Final formula works out to: $T = \frac{7972 + Qt}{11.278 \times S_T} + 1481$ where T equals the flame temperature deg. F, Qt equals the B.t.u.'s brought into furnace by 10.478-lb. of air, and S_T mean specific heat of the combustion gases between 1481° and T deg. F. The various values of Qt taken from Table 1 and the varied values for S_T corresponding to approximate flame temperatures in the second table are substituted in the formula and different temperatures calculated. The final table shows flame temperatures beginning at 3769° F., when air is admitted at 60° F. to 5370° F. when the air is preheated to 2500° F.—EDMUND SHAW

High early strength cements and their increase in strength. P. MAY. *Tonind Ztg.* (Germany), Feb. 9, 1931, V. 55, No. 12, p. 171-3.—Strength measurements up to 5 years show a general increase. Sometimes temporary retrogressions are encountered.—F. O. ANDEREGG

The geology of gypsum. V. CHARRIN. *Rev. materiaux construction trav. publics* (France), March, 1931, No. 258, p. 99-101.—The deposits of gypsum which supply 2 million tons a year around Paris, in Lorraine and Provencales occur either in triasic or miocene formations.—F. O. ANDEREGG

The enumeration of French cement plants. PAUL RAZOUS. *Ciment* (France) Jan. 1931, V. 36, No. 1, p. 13-8; No. 2, p. 59-61.—A description of the properties and list of the different companies and plants making the following cements is given: natural, Roman, artificial (portland), high early strength, alumina, slag (using lime), grappiers (from flint nodules), mixed, white, iron (70 per cent portland clinker with 30 per cent granulated blast furnace slag), and blast furnace cement (contains less clinker than iron cement).—F. O. ANDEREGG

The new cement plant at Neuwied. C. E. PERES. *Tonind. Ztg.* (Germany), March 5, 1931, V. 55, No. 19, p. 275-7.—General plant description.—F. O. ANDEREGG

Testing protective coatings for concrete. P. MECKE. *Tonind. Ztg.* (Germany), March 16, 1931, V. 55, No. 22, p. 322.—To determine the solvent accurately in bituminous preparations 5 g. is placed in a small foil box containing a small roll of gauze. After drying at 100° C. for one hour with the cover removed, the bitumen is distributed over gauze. Then dry to constant weight at 110°. To test the resistance against chemical effects a mortar specimen is made 5x5 in. and a cylinder cemented to it with neat cement. After the cement hardens three coats are applied and the cylinder filled with the solution to be tested.—F. O. ANDEREGG

A new shaft kiln cement plant. HORST LAEGER. *Tonind. Ztg.* (Germany), March 16, 1931, V. 55, No. 22, p. 322-5.—Shaft kiln cement plant erected in Ankara (Angora) with rotating grate.—F. O. ANDEREGG

The different kinds of lime and their handling. F. EISEMANN. *Tonind. Ztg.* (Germany), March 19, 1931, V. 55, No. 23, p. 339-41.—A general description.—F. O. ANDEREGG

Cement synthesis in the four component parallelogram and the degree of lime saturation according to Kühl. M. SPINDEL. *Tonind. Ztg.* (Germany), March 12, 1931, V. 55, No. 21, p. 305-7.—Parallelogram show-

ing composition of cements in terms of lime, silica, alumina and iron oxide can also be used for Kühl's degree of lime saturation.—F. O. ANDEREGG

Industrial heating with ground coal in the mineral industries. J. DEFORGE. *Rev. materiaux construction trav. publics.* (France) Dec., 1930, No. 255, p. 469-73; Jan., 1931, No. 256, p. 5-10; Feb., 1931, No. 257, p. 49-53; March, 1931, No. 258, p. 101-5.—A careful analysis giving advantages and disadvantages.—F. O. ANDEREGG

Modern cement burning. HEINRICH LUFTSCHITZ. *Tonind. Ztg.* (Germany) Feb. 12, 1931, V. 55, No. 13, p. 184-6.—In Schröder shaft kiln dry raw material falls through a shaft kiln heated by coal dust falling through an annular space outside. Also the Rigby patent is used for spraying slurry into a kiln.—F. O. ANDEREGG

Determining the proportions of mortars and concretes. LUDWIG SCHUSTER. *Tonind. Ztg.* (Germany) Feb. 23, 26, 1931, V. 55, No. 16, 17, p. 224-5, 243-4. Examples are given where composition of old mortars and concretes are determined by making analyses for soluble silica, lime, etc. If possible, an analysis of aggregates simplifies solution of problem.—F. O. ANDEREGG

The new cement plant at Rodaun. K. A. GOSLICH. *Tonind. Ztg.* (Germany), March 16, 1931, V. 55, No. 22, p. 317-20.—Description of the erection of a new, dry process cement plant on site of the old one.—F. O. ANDEREGG

German specifications for alumina cement. HUGO VIERHELLER. *Tonind. Ztg.* (Germany), March 16, 1931, V. 55, No. 22, p. 325-6.—Fineness: not more than 2 per cent on the 75 and 15 per cent on 180 mesh sieve. Tests to be made at 15 to 20° C. Storage of specimens 24 hr. in damp closet and then under wet cloths. Minimum strengths are: at 24 hr., at 28 da. wet and at 28 da. combined storage: compression, 400, 500, 600 and tensile; 25, 30 and 40 kg. per sq. cm.—F. O. ANDEREGG

Rapid determination of magnesia in portland cement. CH. ROGOZINSKI. *Tonind. Ztg.* (Germany), March 23, 1931, V. 55, No. 24, p. 355-6.—After removing the silica, *N* NaOH is added till a precipitate forms and the supernatant liquor is clear. Filter into an excess 0.2 *N* HCl and titrate back with 0.2*N* NaOH and phenolphthalein—F. O. ANDEREGG

Measures for securing cement of uniform quality. W. SACH. *Tonind. Ztg.* (Germany), March 9, 1931, V. 55, No. 20, p. 291-3.—Proper feeding, weighing and mixing, obtained with suitable automatic apparatus are useful in securing uniform quality.—F. O. ANDEREGG

The uniformity of concrete and its control on the job. FRITZ EMPERGER. *Tonind. Ztg.* (Germany), March 30, 1931, V. 55, No. 26, p. 382-3—Cubes and beams are made and broken at seven days.—F. O. ANDEREGG

Alumina cement. M. KAUCHTSCHISCHWILI. *Siemens-Z.* 1930, No. 9, 10; *Tonind. Ztg.* (Germany), Dec. 18, 1930, V. 54, No. 101, p. 1565-7; No. 102, p. 1585-6.—Description of general properties and of manufacture.—F. O. ANDEREGG

Studies on high-iron oxide cements—Part 1. SHOICHIRO NAGAI AND KEI-ICHI AKIYAMA. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), Feb., 1930, V. 33, Supplemental Binding No. 2, p. 47-9B.—Two high-iron oxide cements, one of the iron cement type and one of Kuhl cement type were prepared of two pozzuolanas, analyses of which are given and limestone. Composition and properties of burned clinkers were studied and compared with commercial products. Normal and small-piece testing method were used for determination of compressive strength. (cf. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), 1930, V. 33, p. 286-90, 421-8; JOURNAL A. C. I., Feb., 1931, V. 2, No. 6, *Abstracts* Sect., p. 162.)—A. E. BEITLICH

Cement-mill expansion program reflects vision of designing engineers. W. E. TRAUFFER. *Pit and Quarry,* March 11, 1931, V. 21, No. 12, p. 67-78.—Improvements in plant of Keystone Portland Cement Co., at Bath, Pa., include enlargement of stone storage, a second overhead traveling crane,

two raw-grinding and two finish-grinding mills, additional slurry silos, two kilns and stacks, enlargement of the coal-pulverizing equipment, additional cement-storage silos and packhouses, and enlargements to crusher, mill and kiln buildings. Raw mills are opposite stone storage, coal mill is opposite coal storage, discharge ends of kilns and finish mills are opposite clinker storage, and slurry silos are between raw mills and feed ends of kilns. All raw material comes from one quarry and as sent to mill is practically correct composition for high grade cement.—A. J. HOSKIN

Microscopical, optical and X-ray investigations concerning the question: "What is alit?" I. WEYER. *Zement* (Germany), Jan. 29, 1931, V. 20, No. 5, p. 96-100.—Alit, separated from commercial clinker, was found to contain considerable amounts of alumina. This fact led to beliefs that tricalcium aluminate can enter into combination with tricalcium silicate. In experiments made to study problem, various mixtures of pure tricalcium silicate and tricalcium aluminate were mixed and burned several times at different temperatures and products investigated by X-ray analysis. None of mixtures showed any characteristic lines besides lines for tricalcium aluminate and tricalcium silicate. In mixtures with only 6.89 per cent tricalcium aluminate (16:1), it was impossible to detect this compound. Microscopic studies showed that a recrystallization of tricalcium silicate takes place in such melts which fact does not change its optical characteristics.—A. E. BEITLICH

Petrographic investigation of fused high alumina cements. KATSUZO KOYANAGI. *Kogyo Kwagaku Zasshi, J. of Soc. Chem. Ind.* (Japan), Sept., 1930, V. 33, Supplemental Binding, No. 9, p. 352-8B.—Investigations and experiments by Gruen, Dyckerhoff and Biehl in studies of chemical constitution of high alumina cements are described. Efforts were made by author to prepare synthetically a melt of composition: 47 per cent CaO, 44 per cent Al_2O_3 and 9 per cent SiO_2, which is similar to French Ciment fondu. After different heat treatments thin sections were studied under microscope and optical properties were determined. Furthermore melts of following compositions were prepared: $3CaO.5Al_2O_3$, $CaO.Al_2O_3$, $3CaO.Al_2O_3$ and $5CaO.3Al_2O_3$ and microscopically investigated.—A. E. BEITLICH

Studies of the method by Lawrence Smith for the determination of alkalies. CURT PRUSSING. *Zement* (Germany), April 16, 1931, V. 20, No. 16, p. 360.—The method for determination of alkalies which was proposed for German standard specifications for chemical analysis of portland cement (Burchartz, *Zement* (Germany), March 19, 26, 1931, V. 20, No. 12-13, p. 258-60, 290-2), was checked and it was found that temperature for ignition of alkalies is too high. Great amounts of alkalies are volatilized. Mixtures of sodium chloride, potassium chloride and ammonium chloride were ignited at 932 to 1922° F. and loss on ignition was determined. Author proposed heating of sample in electric crucible furnace provided with a rheostat to regulate temperature between 700 and 750° F.—A. E. BEITLICH

A mixed cement of low solubility of portland cement and arsenic trioxide. DONOVAN WERNER AND STIG GIERTZ-HEDSTROM. *Zement* (Germany), April 23, 1931, V. 20, No. 17, p. 384-8.—Investigation of possibilities of use of a mixture of portland cement and arsenic trioxide yielded following: Mixed cement with 30 per cent As_2O_3 is quick setting (5 minutes); it can be made normal setting by heating in closed container. Compressive and tensile strengths are lowered by additions from 10 to 15 per cent As_2O_3; with increasing additions strength increases too and reaches maximum with 30 per cent. Above 30 per cent strength decreases again. Strength is always slightly lower than strength of pure cement. Solubility of lime of portland cement is greatly reduced by additions of As_2O_3. Best composition is 70 per cent portland cement and 30 per cent arsenic trioxide which produces, after heating, a very slightly soluble normal setting cement with strength properties above limits of specifications.—A. E. BEITLICH

The determination of the uncombined lime. Supplemental discussion of the glycerol-tartaric acid method of H. Rathke. K. SCHINDLER. *Zement* (Germany), April 23, 1931, V. 20, No. 17, p. 389-90.—A new procedure is described which overcomes difficulties and inaccuracies of method by Rathke who modifies Emley's method by using tartaric acid instead of ammonium acetate for titration of uncombined lime. Greatest source for errors is tendency of calcium glycerate to crystallize before all calcium oxide is dissolved thus preventing complete solution. It affects especially standardization of tartaric acid. Procedure is same for cement and similar materials.—A. E. BEITLICH

Investigation of portland cement and its constituents by means of measurements of vapor pressure. Part 2. F. KRAUSS AND G. JOERNS. *Zement* (Germany), April 2, 9, 1931, V. 20, No. 14, 15, p. 314-7, 341-3.—Preliminary investigation and experiments were reported in previous article (*Zement* (Germany), Nov. 6, 1930, V. 19, No. 45, p. 1054-5; JOURNAL A. C. I., Feb. 1931, V. 2, No. 6, *Abstracts*, p. 164). Work was continued and vapor pressure curves determined for gypsum, calcium carbonate, calcium hydroxide and hydrates of silica, alumina and ferric oxide. Synthetic melts of tricalcium silicate, tricalcium aluminate and compound $8CaO.2SiO_2.Al_2O_3$ were prepared from pure raw materials and hydrated. Products of hydration were decomposed and characteristics of vapor pressure curves were studied. Similar tests were conducted with portland cement. Work will be continued.—A. E. BEITLICH

Contribution to the hardening problem of portland cement. HANS KUHL. *Zement* (Germany), March 12, 1931, V. 20, No. 11, p. 234-9.—Contrary to Tippmann's theory, (cf. *Zement* (Germany), Dec. 25, 1930, V. 19, No. 52, p. 1225-34) chief products of hydration of portland cement are calcium hydrosilicates, not calcium hydroxide and silica gels. Cements of normal consistency do not have a high viscosity. Special consideration is given to description of 2 different modifications of calcium hydroxide. Existence of amorphous calcium hydroxide with a specific gravity of 2.08 is denied. Experiments for preparation of this form were made according to Tippmann's directions but with negative results. Cement was mixed with water and with weak and saturated gypsum solutions. Products of hydration were examined under microscope at frequent intervals. No distinct difference could be detected. Author obtained small crystals of $Ca(OH)_2$ from calcium oxide and water which formation was claimed to be impossible by Tippmann. Statement that 2 modifications of calcium hydroxide are chief constituents in hardening process is attacked. This property is attributed to calcium hydrosilicates. The microscopic method used by Tippmann is criticized. Theoretical deductions and experimental findings do not harmonize.—A. E. BEITLICH

The effect of different kinds of gypsum on setting of cements. KATSUZO KOYANAGI. *Zement* (Germany), March 5, 1931, V. 20, No. 10, p. 215-7.—In experiments with a portland cement clinker and gypsum, hemihydrate, dehydrated anhydrite and natural anhydrite, retarders were either ground together with clinker or fine ground materials were mixed together in a laboratory size mixer. Setting properties of mixtures with 0 to 10 per cent SO_3 were determined. A certain percentage was found where retarding effect is greatest. This is 5 per cent SO_3 for natural anhydrite, 2 per cent for gypsum, 1.5 per cent for hemihydrate and 1.2 per cent for dehydrated anhydrite. Effect of retarders was greater when mixed with fine clinker than in case where both were ground together. Experiments A. Heiser (cf. *Zement* (Germany), July 1930, V. 19, No. 29, p. 679-80; JOURNAL A. C. I., Oct. 1930, V. 2, No. 2, *Abstracts*, p. 34), yielded entirely different results. His tests were made on large scale under different temperature conditions and his opinion is supported by Grimm, Forsen and Tippmann.—A. E. BEITLICH

Effect of storage on properties of standard cements. RICHARD GRUEN AND H. MANECKE. *Zentralblatt der Bauverwaltung* (Germany), 1930, V. 50, p. 485, reviewed in *Zement* (Germany), Jan. 22, 1931, V. 20, No. 4, p. 86.

—Storage of cements at 18° F. resulted in decrease of about 8 per cent in 7-day tensile strength and increase of about 20 per cent in 3-day compressive strength. Storage in closed room had no harmful effect on strength properties. Careless storage in single sacks in open shed led to decrease of tensile and compressive strength, especially when lumps were not removed by sieving. Greatest losses after 3 months storage were 17 per cent for tensile strength and 14 per cent for compressive strength.—A. E. BEITLICH

Loss in strength of cement through storage. WALTER OBST. *Betonwerk*, March 29, 1931, V. 19, No. 13, p. 173.—Cement that does not deteriorate in storage is unknown, but fresh cement is not always constant in volume and a period of storage is helpful. Storage in warehouse in a thick layer and periodic turning over by plowing does much to prevent "efflorescence." This method also increases strength. For best practice cement should not be stored more than three months and never longer than nine months. Twelve months decreases strength up to 30 per cent. Storage rooms should be free of draft, cement should be placed on planking raised up from floor and bags of cement should be placed free of wall and piled not higher than 10 high. Paper bags are better than cloth bags for keeping cement in good condition.—H. FRAUENFELDER

Changes of setting time of portland cement. HELLMUT WEITHASE. *Zement* (Germany), Feb. 26, 1931, V. 20, No. 9, p. 187-92.—Thirty references are given to papers dealing with changes in setting time of portland cement during storage. Phenomena are explained in many different ways. To clear this question comprehensive tests with 55 cements were undertaken. Cement was spread in thin layers of about 1 or 2 in. and setting times were determined within very short intervals of storage. Certain very fine cements show earlier initial set in air storage but retarded final set. Changes seem to be caused in the first place by chemical composition, especially lime content of cement and also by effect of carbon dioxide of air on cement.—A. E. BEITLICH

The Rigby-spray method in cement industry. S. I. M. AULD. *Zement* (Germany), Feb. 12, 1931, V. 20, No. 7, p. 142-4.—Greater heat economy and increased efficiency is obtained by spraying slurry into kilns by means of compressed air. Great surface of dispersed fine materials facilitates drying. Kiln gas temperature is lowered causing less coal consumption and smaller radiation losses. Calcination zone of kiln is as long as in ordinary kiln. Only 26 per cent of total length is used for drying. Nozzles under pressure of 5 atmospheres can be easily replaced without interruption of operation and at low costs. Installation of fan is advisable to compensate for decreased draft on account of lower temperature of kiln gases.—A. E. BEITLICH

The last word in the alit problem. A. GUTTMANN AND F. GILLE. *Zement* (Germany), Feb. 12, 1931, V. 20, No. 7, p. 144-7.—After studying latest research results of American and German investigators on subject of existence of tricalcium silicate and presenting data on X-ray diffraction patterns in several tables, authors draw following conclusions. (1) No doubt exists about existence of tricalcium silicate. (2) Alit, chief constituent of high lime portland cements, is neither a dicalcium silicate which is rich in free lime (Dyckerhoff), nor a solid, solution of a high lime aluminate, (Jaeneckeit), and tricalcium silicate (Kuehl), nor a solid solution of chiefly tricalcium silicate and tricalcium aluminate (Guttmann and Gille), nor a solid solution of Jaeneckeit and dicalcium silicate (Jaenecke), nor is dicalcium silicate chief constituent of alit (Nacken), but alit is tricalcium silicate. (3) Part of alumina is combined as celit (chiefly $4CaO.Al_2O_3.(Fe,Mn)_2O_3$). Remaining part is present as tricalcium aluminate and partly as $5CaO.Al_2O_3$.—A. E. BEITLICH

Fine cement. A. B. HELBIG. *Zement* (Germany), Jan. 22, 1931, V. 20, No. 4, p. 75-8.—Contrary to findings of Hans Kühl and A. Hauenschild, cement strength increases with increasing fineness, especially in early ages. Decrease in strength which was observed by above investigators in cases of extremely fine cements, is due to a partial hydration of fine particles by moisture of air in air separator. Commercial cements were separated into several fine fractions

by means of a large scale air separator. Tables show fineness of separation, water for normal consistency and compressive and tensile strength data up to 28 days in water and combination storage. Fineness affects water permeability. Case is cited where fine grinding increased strength in ratio 1:1.9 while water permeability was decreased in ratio 56:1. Diagram shows relation between particle size of cement and best suitable diameter of steel balls in mill. —A. E. BEITLICH

Fine cement. HANS KUHL. *Zement* (Germany), Feb. 19, 1931, V. 20, No. 8, p. 169-70.—In answer to article by A. B. Helbig in *Zement* (Germany), Jan. 22, 1931, V. 20, No. 4, p. 75-8, author states that Helbig did not work with cements of such extreme fineness and therefore did not notice a decrease in strength in very fine range. Inner surfaces of cements, used by Helbig, were calculated by means of formula derived by Kuhl and Tokune. Finest cement had surface of 216.5 sq. in. A drop in strength was observed only in cases of cements with inner surfaces of 500 sq. in. and higher. Cements investigated by author were not affected by moisture; air for separation was absolutely dry.—A. E. BEITLICH

New Mexican cement plant serves west coast territory. *Concrete*, March, 1931. V. 38, No. 3, p. 77.—Wet process cement plant is nearing completion at Hermosillo, Sonora, Mexico. Present capacity is 500 barrels per day (one 8 by 150-ft. kiln), provisions being made for increasing capacity at any time. Raw materials are stone and clay. There are two gyratory crushers (one 12 in. and one 4½ in.), and two 6 by 22-ft. compartment mills (one for raw and one for finishing grinding). Power is furnished by three 360 h. p. Diesel engines direct-connected to Westinghouse generators.—V. E. BUTLER

Technical progress reports. Volume 25. Cement. "Technische Fortschritts Berichte. Band 25. Zement." F. WECKE, 1930, Th. Steinkopff, Dresden and Leipzig, (Germany), RM. 6.00. Reviewed in *Zement* (Germany), Feb. 12, 1931, V. 20, No. 7, p. 156.—Valuable data are presented on portland cement, raw materials, manufacture and testing, and high early strength cements, special cements and blast furnace slag cements are discussed. Numerous literature references, complete up to 1929 aid study of progress and problems in cement manufacture and cement chemistry. Statistical data are furnished on import and export trade since 1900.—A. E. BEITLICH

The "Delta" rocker chute. H. WALTER. *Zement* (Germany), Feb. 26, 1931, V. 20, No. 9, p. 201-2.—New improved rocker chute is especially suitable for transportation of large amounts of dusty, pulverized and broken materials, Design and construction make operation very economical. Machine is applicable for conveying of hot clinker in cement industry.—A. E. BEITLICH

The degree of lime saturation. HANS KUHL. *Zement* (Germany), Feb. 5, 1931, V. 20, No. 6, p. 123-5.—In criticism of proposed changes of "degree of lime saturation" by Hess (cf. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 28-32; JOURNAL A. C. I., April, 1931, V. 2, No. 8, *Abstracts*, p. 214), author agrees with proposal to express degree of lime saturation by a number 100 times as big as previously used but he criticizes attempts of Hess to make changes in derived equation, especially to give numbers with too many decimal places. Latter procedure would give a false impression of accuracy of calculation method.—A. E. BEITLICH

New cement plant in Dumesnil (Argentina). *Zement* (Germany), Feb. 5, 1931, V. 20, No. 6, p. 134.—At modern wet process portland cement plant recently completed in close vicinity of limestone quarries near Dumesnil, aerial cable ways deliver limestone and clay in cars. Clay slurry is ground together with limestone. Material passes through kiln bins into 9 rotary kilns, 223 ft. long and 9.8 and 11.8 ft. in diameter. Each kiln produces 220 tons of clinker in 24 hours. Fuel consumption is 44 tons of crude oil. Finished product is pumped to cement storage bins. Plant is equipped with very modern cement laboratories, machine shops, water tower, cooling tower and modern power house.—A. E. BEITLICH

Finding undeveloped sources of fuel for cement plants. E. T. ELLIS. *Concrete*, Feb., 1931, V. 38, No. 2, p. 91.—Certain so-called low grade fuels are apt to be overlooked by cement manufacturers, but can, if manipulated in certain easy ways, be utilized advantageously for burning, either alone or combined with coal and other materials usually employed. The compositions and names of these many materials vary widely in different parts of the world, but analyses in many instances are available, and by examining these together with materials themselves it is possible to judge whether any offer of such materials should be declined or accepted. Materials discussed are: Anthracite culm, anthracite slush or silt, "batts" from coal cleanng dumps, colliery slurry, colliery smudge, refuse from tipple picking tables, steam duff, tip breeze, and washery waste.—V. E. BUTLER

Discussion of the new proposed German standard specifications for reinforced concrete. OTTO GASSNER. *Zement* (Germany), Feb. 26, 1931, V. 20, No. 9, p. 198-200.—Changes and additions to tentative specifications of the German Committee for Reinforced Concrete, Part A, Specificatons for Construction of Structures of Reinforced Concrete are criticized. Definition of standard cement is slightly changed and high early strength cements are included. Natural cements are not mentioned. Exact control of gradation of aggreates, especially for important structures, wet concrete and under-water cast concrete are demanded. Use of broken volcaneous materials and pumice are admitted as aggregates. More consideration is given to impurities of aggregates. No boiler cinders are allowed for reinforced concrete. In structures exposed to high temperatures reinforced concrete must contain aggregates with small expansion coefficient and low heat conductivity. Quartzy aggregates should not be used in chimney construction. Insufficient definition of degree of impurity of mixing water is criticized.—A. E. BEITLICH

Only active cement plant in Arkansas. J. F. KAUFMAN. *Rock Products*, March 28, 1931, V. 34, No. 7, p. 41.—Distinguishing feature of operation of Arkans Portland Cement Co.'s mill at Okay, Ark. is filtering of slurry in three 12-disk filters with 7200 sq. ft. filtering surface. Without filtration the slurry, made from chalk and clay, had a moisture content of 48-50 per cent and was hard to handle because of viscous nature. Filtration reduced moisture to 28½-29 per cent. Filter cake is fed to kiln by a Bessemer feeder. Capacity of filter depends on temperature of slurry. Heat of waste gases brings the water to 150° F. Cast iron lifters in the kiln keep the slurry moving forward and prevent the formation of mud rings.—EDMUND SHAW

Contribution to the question of kilns for the manufacture of fused cements. E. SCHIRM. *Zement* (Germany), Feb. 5, 1931, V. 20, No. 6, p. 118-23.—Various kinds of high alumina cement kilns have their advantages and disadvantages (1) In shaft kiln with water jacket, raw mixture consisting mostly of limestone and bauxite becomes pasty which fact causes considerable difficulty. (2) Improved shaft kiln has separate horizontal fusion chamber. Material in vertical part is only preheated and not fused. (3) Still better is kiln so constructed that pasty zone is prevented. (4) Another shaft kiln consists of 3 different chambers. Material is heated and partly decomposed in top chamber, then fed to second section on a water cooled grate. (5) Greatest difficulty with rotary kiln is formation of back rings which may block entire kiln. (6) An improvement was developed in France by installing a longer kiln head with hottest part of flame where material leaves kiln. (7) Better heat economy is obtained by installing a recuperator. (8) Kiln has been designed in which bauxite and limestone are heated separately in 2 concentric tubes. Heated materials are emptied into hearth furnace where mixture is burned completely. —A. E. BEITLICH

Chemical reactions in the setting of cement. LINCOLN T. WORK AND FRANKLIN P. LASSETER. *Concrete*, March, 1931, V. 38, No. 3, p. 81-86, No. 4, p. 89-92, No. 5, p. 79-84.—Investigation of chemical reactions that take place during setting and hardening of portland cement is abstracted by the authors.

In studying state of combination of water, following methods were tested: 1. Extraction with absolute alcohol. 2. Distillation using benzol, toluol and xylol. 3. Vacuum drying. 4. Oven drying in dry air at 90, 105 and 130 deg. C. The test of oven drying at 105° C. was chosen as standard. Total water was determined at 850° C. Under those conditions a small amount of moisture will remain, but calcium sulfate should not be decomposed appreciably. Therefore, difference representing combined water should be essentially correct. Ammonium acetate method for lime in clinker has been adapted to measure hydrated lime in a set cement. Samples with varying water-cement ratios using each of the compounds tricalcium aluminate, tricalcium silicate, and β dicalcium silicate, and four commercial cements, were studied to ascertain nature of chemical reactions and rate of hydration and hydrolysis during setting and hardening. Tricalcium aluminate hydrates to $3CaO.Al_2O_3.6H_2O$ and this on calcination yields lime and an apparent residue of $5CaO.3Al_2O_3$. This hexahydrate can be partially dehydrated in vacuum at 240-250° C. With water-cement ratios of 0.5 and greater, tricalcium aluminate was practically completely hydrated to hexahydrate in 28 days. Tricalcium silicate reacts both by hydration and hydrolysis. During early stages of hydrolysis approximately one molecule of water combines with silicate for each molecule of lime liberated. Beta dicalcum silicate was shown to react chiefly by addition of water and released very little lime for several months. Pure compounds and cements yielded a typical curve for percentage of combined water against water-cement ratio. Starting at the origin, values of combined water rose with water-cement ratio up to a ratio of 0.2 to 0.4, after which they became practically horizontal. In case of the aluminate, reaction at low water-cement ratio consumed all of the water, but that was not found to be the case with other pure compounds or with cements. Hydration was rapid with aluminate, slower with tricalcium silicate and very much slower with dicalcium silicate. Tricalcium aluminate yielded no lime in setting. Tricalcium silicate yielded lime more or less similar in amount to combined water value and beta dicalcium silicate yielded but small quantities of lime up to three months. Combined water values for cements were similar to those for tricalcium silicate but rate of hydration varied directly with fineness. Lime values were somewhat similar, save for a dip in the curve at low water-cement ratios which appears to be due to selective hydration of aluminate. Comparison of hydration and hydrolysis of cements was made with strength of a standard concrete using same cements at water-cement ratio of 0.55. Fine cements reacted more completely in early stages and developed high strength. Coarse cement reacted slowly at first but for a longer time. Later reaction did not develop an equivalent strength.—V. E. BUTLER

Constitution of portland cement studied by X-ray method. L. T. BROWNMILLER AND R. H. BOGUE. *Concrete*, Feb. 1931, V. 38, No. 2, p. 85, March, 1931, V. 38, No. 3, p. 89.—Objectives in research were (1) to obtain additional information on theories established by other investigators, and (2) examination of a large number of commercial clinkers by x-ray and chemical methods to find out exactly what compounds could be positively identified in each and nature of agreement between such x-ray analysis and constitution as computed from chemical analysis. It was necessary to determine efficiency of x-ray method to decide pattern of each compound in presence of other compounds of cement. An examination of composition $3CaO + SiO_2$ proved that $3CaO.SiO_2$ exists and can be formed by heating together, under proper conditions, of a properly proportioned mixture of lime and silica. An examination of the system $3CaO.SiO_2$—$2CaO.SiO_2$—$3CaO.Al_2O_3$ shows that solid solution does not occur between either of above silicates and aluminate in large amounts. Mixtures at equilibrium contain only those three compounds. In commercial cement clinkers free CaO was not found by x-ray method. Study of identification of that compound indicates that a percentage of CaO of 2.5 could be recognized. Therefore, it is demonstrated that free CaO is not commonly present in commercial clinkers in amounts as high as 2.5 per cent. The x-ray

diffraction patterns of 28 commercial portland cement clinkers, representing many types of raw material and processes of manufacture—both domestic and foreign—were obtained. Results obtained by x-ray methods define major constitution of portland cement clinker and indicate most abundant constituents are tricalcium silicate and beta dicalcium silicate; that there are normally present, in addition, tricalcium aluminate, tetracalcium alumino ferrite and magnesia; and that free CaO is not normally present in amounts as great as 2.5 per cent.—V. E. BUTLER

Free lime in portland cement clinker and soundness of cement. KATSUZO KOYANAGI. *Rock Products*, March 28, 1931. V. 34. No. 7, p. 74.—There are two opinions of free lime in cement clinker. Rohland thinks unsoundness comes from lime that is neither dissolved in other constituents nor chemically combined, and Kuhl thinks that lime in cement is never free and that unsoundness comes from "explosive grains" containing excess lime in solution or combination. Japanese cement burners test clinker by touching it to the tongue. If saliva is absorbed quickly clinker is thought unsound. To test this, Emley's method of determining free lime, as modified by Rathke has been used by the author in tests of sound and unsound clinkers which included determinations of porosity and free lime. Porosity was determined by immersing in water-free turpentine oil for 24 hr. and then boiling ½-hr. and cooling and weighing. Soundness was determined by water test, boiling and a modification of LeChatelier's test. Further research showed clinkers could have low porosity and high free lime content. These were hard burned clinkers with high iron oxide content except one with extraordinarily low lime content and overburned. In mixtures of sound with unsound cement, with free lime running from 0.45 to 0.81 per cent, samples were sound; from 0.99 to 1.88 per cent, samples were unsound, increasingly so as free lime increased. A third series of tests showed effect of storing unsound cement on paper in laboratory so that free lime had a chance to carbonate. The temp. was 73-86° F. and the moisture, 80-100 per cent normal. In 3 da. free lime fell from 2.44 per cent, to 1.49 per cent and in 40 da. to .30 per cent. All samples taken at 20 da. and after were sound. At a fineness of 4 per cent on a 4900-mesh (metric) sieve cement becomes unsound in boiling test when free lime exceeds 1 per cent and unsound to both boiling and water tests when it exceeds 2.2 per cent. Whether this free lime is absolutely free or is combined in explosive grains is not known exactly, but it is certain that it affects soundness of cement very much.—EDMUND SHAW

A tentative modification of the free lime method. H. R. BRANDENBURG. *Rock Products*, March 14, 1931, V. 34, No. 6, p. 68.—Use of barium chloride as a reagent to increase solubility of CaO in glycerol-alcohol mixture in determining free lime is suggested. The $BaCl_2$ is made anhydrous by holding at 140-150° C. for several hours. Then it is cooled, ground and stored in a desiccator. Tests were agitated on the base of a Ro-tap screening machine, to which had been clamped a sheet metal holder that would take six flasks. Standards were run on freshly calcined CaO, from .05 to 25 g., with and without $BaCl_2$. Solution of CaO was extremely rapid, permitting additions of acetate solution to be made at 2 to 5 min. intervals, care being taken not to run in an excess. CaO values were found to be a trifle higher than with standard method. On materials requiring from 2.0 to 2.5 cc. of the acetate solution, time with $BaCl_2$ varied from 25 to 40 min. as against 2½ to 4 hr. by the standard method. Method has been used successfully on clinkers, hydrated limes and plasters.—EDMUND SHAW

Researches on the rotary kiln in cement manufacture. Part 14. Flame temperatures obtained in practice in the cement rotary kiln. GEOFFREY MARTIN. *Rock Products*, March 14, 1931, V. 34, No. 6, p. 41.—Actual temperatures observed by the B. P. C. R. A. by optical pyrometer were 2759, 2692, 2536 and 2835° F. Prof. Nacken found a temperature of 2606° F. and E. C. Soper 2587° F. with the same instrument. Prof. Nacken's figures are taken as the mean flame temperature in ordinary kiln. It is assumed that

11.278 lb. combustion gas is produced by burning 1 lb. coal in t sec. In insulated enclosure, with 10.478 lb. air preheated to 400° F. gas will rise 3977° F. In the actual kiln so much heat is lost by radiation, conduction and convection that temperature is reduced to 2600°. Heat is lost by (1) external radiation, (2) radiating from hot flame to cooler parts of kiln and (3) communicating by conduction and convection to material in clinkering zone. (1) is waste but (2) and (3) can be usefully employed under limitations. At clinkering temperature clinker tends to evolve heat. In practice amount of clinker turned out of flame sinking through different temperatures can be calculated.—EDMUND SHAW

Researches on the rotary kiln in cement manufacture. Part 15. Weight of clinker producible using combustion gases of different flame temperatures and supplying 10.478 lb. air per 1 lb. of standard coal burned. GEOFFREY MARTIN. *Rock Products*, March 28, 1931, V. 34, No. 7, p. 68.—Main heating agent in kiln is hot gases into which powdered coal oxidizes. Each pound coal yields 11.278 lb. gas which, in the ordinary cement kiln, starts at 2600° F. and imparts its heat to material as it travels. The kiln may be divided into two parts, A where the temp. is above 1481° F. and B where it is below this. Limestone and chalk will decompose only in A. Heat in B is useful in drying and heating materials preparatory to clinkering in B. Quantity of clinker formed is measured by the amount of heat absorbed by the material in A between 1481° F. and the clinkering temp., 2498° F. This quantity of heat, Q equals $11.278 \times S \times (T - 1481°) \times$ B.t.u., where T is the max. temp. and S is specific heat. To form 1 lb. clinker requires 918.6 B.t.u., so weight of clinker W, formed by burning 1 lb. standard coal to its equivalent of 11.278 lb. gas equals Q, divided by 918.6. If coal is burned in t sec., amount of clinker produced in 1 sec. is $\frac{W}{t}$. As ideal kiln would require only 6.36 tons coal, ordinary kiln making 100 tons clinker for 28 tons standard coal is only 22.7% efficient. Computed results show that heating in kiln is by hot gas and that clinker output is measured by heat loss of gas as it travels down kiln. —EDMUND SHAW

The upper SO_3 limit in portland cement. F. O. ANDEREGG. *Rock Products*, Feb. 28, 1931, V. 34, No. 5, p. 76.—Better retardation of finely ground high-early-strength cement is reason for adding more gypsum to clinker than has been permitted in past. Question arises as to safe upper limit of SO_3 since excess gypsum is known to reduce durability of cement, probably by crystal growth. Tests were made with cement flour, air-separated so practically all particles were below 10 microns in diameter. Oversize was reground and separated to give a cement containing a fraction less SO_3. When cement is gaged with water a low sulphate form may be present at first but it changes over to more stable form which may grow into crystals large enough to be identified under microscope. In view of the test results the proposed A. S. T. M. specifications limiting SO_3 to 2½ per cent in early-strength cements appears conservative, but greater amounts are undesirable. Alumina content of clinker should be kept within reasonable limits. From a study of the rate of hardening of specimens made from cement flour it is thought that indurating reactions of silica gel play important role in hardening of this cement.—EDMUND SHAW

MISCELLANEOUS

Separation of calcium and magnesium by molybdate method. R. C. WILEY. *Ind. Eng. Chem.*, Analytical Edition, April, 1931, V. 3, No. 2, p. 127-9.—Calcium molybdate is quite insoluble in a solution that is nearly neutral. Calcium may be determined accurately by precipitating as molybdate. Presence of residual ammonium molybdate in washings from calcium molybdate does not prevent precipitation of magnesium as magnesium ammonium phosphate, and presence of ammonium salts does not interfere with determination of calcium as molybdate. Calcium and magnesium may be

determined in much less time when molybdate method for calcium is used than when calcium is precipitated by the oxalate method.—ROY N. YOUNG

Protective coatings. KARL MEYER. *Zement* (Germany), Jan. 29, 1931, V. 20, No. 5, p. 109-10.—It is claimed that protective media such as paraffine and asphalt, proposed by Goslich (cf. *Zement* (Germany), June 1930, V. 19, No. 24, p. 567-8; *Journal A. C. I.*, Oct. 1930, V. 2, No. 2, *Abstr.*, p. 38), do not give satisfactory service for protection of concrete and reinforced concrete. Better results can be obtained with modern cold asphalt paints. Goslich claims that coatings consisting of hydrocarbons (paraffines) are highly resistant in aggressive waters and moist air. Several examples are cited where such media have been used with great success.—A. E. BEITLICH

Pulverized coal fuel in the mineral industries. J. DEFORGE. *Rc. materiaux construction trav. publics*, (France), December 1930 to March 1931.—Conclusions drawn upon discussing in detail economy of pulverised coal as a fuel are: Advantages (a) more complete evolution of heat corresponding to calorific value of the fuel; (b) possibility of utilizing inferior grade fuels, not acceptable for use otherwise. (c) simplification of firing; instantaneous ignition and extinction; a specially valuable ease of operation under certain conditions of installation. Disadvantages (a) accident risk; (b) flue dust difficulties; (c) the high cost of installation. Accidents can be greatly reduced in using adequate precaution. Special devices cope with flue dust problem. High initial cost is frequently more than compensated through economies in using a cheaper fuel or through lower fuel consumption. Though in every case, a study should be made of special conditions pertaining to installation in question, French industries should take advantage of this most rational method of utilizing coal.—M. A. CORBIN

Mechanism of combustion of individual particles of solid fuels. DAVIS F. SMITH AND AUSTIN GUDMUNDSEN. *Ind. Eng. Chem.*, March, 1931, V. 23, No. 3, p. 277-285.—Descriptions in detail of unique apparatus and methods employed in a fundamental study of combustion of solid fuel are included. Effects of varying particle size, air velocity, temperature and humidity on rate of combustion of solid fuel under carefully controlled conditions have been investigated and considerable light is thrown upon the mechanism of these important reactions. Briefly the procedure consists of heating a weighed sphere of fuel to the desired temperature in inert gas, suddenly blasting the particle with an air stream of given velocity and temperature for a very short interval of time, quickly quenching the particle in inert gas, again weighing to determine amount of reaction, and carefully obtaining records of particle surface temperature during combustion. Most of work was done with nearly pure carbon shaped from electrode carbons such as used in arc lamps for projection. In addition, however, fuels of known ash content were investigated. Following conclusions were reached: (1) The specific surface-reaction rate for carbon spheres burned in dry and moist air is a complex function of particle size. It is enormously larger for a small particle than for a large one. (2) The temperature of the surface increases as the particle is reduced in size. (3) At lower velocities, below about 4 ft. per sec. as measured at 24 deg. C., reaction rate increases rapidly with increase in velocity, independent of other variables. This decreases continuously as the velocity increases until in high-velocity range a large increase in velocity increases reaction rate only slightly. (4) Size of particle, independent of other variables, has an effect on specific surface-reaction rate; that is, for the same air velocity and same surface temperature, a small particle has a higher specific surface-reaction rate than does a larger one. (5) Carbon spheres of surface area 70 to 10 sq. m.m. burn faster in dry air than in moist air. (6) The surface temperature is higher when the particles are burned in moist air. (7) An increase in surface temperature, for particles burned in dry air, increases the reaction rage—that is, the temperature coefficient is positive. Maximum temperature coefficient is associated with small particle size, high air velocity, and high surface temperature. (8) An

increase in surface temperature for particles burned in wet air at low velocities decreases the reaction rate, but for higher velocities the reaction rate increases with rise in surface temperature. (9) A mechanism explaining the observed effects of water vapor on the combustion of electrode-carbon spheres burned in wet air is suggested.—ROY N. YOUNG

Accurate air separator for fine powders. PAUL S. ROLLER. *Ind. Eng. Chem.*, Analytical Edition, April, 1931, V. 3, No. 2, p. 212-16.—Apparatus separates quantitatively a 1-kg. charge of fine powder into a series of fractions beginning 0-2.5 microns in size. Except for finest fractions, at or below 5 microns, where attrition by air current takes place in case of soft powders, particle sizes separated are very homogeneous within limits given by Stokes' law. Several causes affect rate of separation, but most important is that of rate of air flow. Under similar conditions rate of separation is proportional to air flow. Depending on the latter, initial rates of separation of particle-size fractions have been made up to 135 grams per hour at a flow of 140 liters per minute. Continuous separation can be effected by use of an offset separator tube with separate collection of oversize. At a 30-micron particle size cut of a portland cement powder, with an air flow of 500 liters per minute, equivalent rate of feed was 5.4 kg. per hour, while rate of recovery was 0.92 kg. per hour. —ROY N. YOUNG

Effect of mica and iron-mica on strength of mortar and concrete. G. KATHREIN. *Zement* (Germany), Feb. 19, 1931, V. 20, No. 8, p. 174-7.—Experiments at Institute for Mineralogy and Testing Materials at Technische Hochschule in Vienna (Austria) revealed interesting facts concerning effect of mica on concrete properties. Sand in 1:3 mortar specimens was replaced in certain proportions by mica. Compressive strength is lowered by 1 per cent mica; greater percentages cause rapid decreases in compressive strength. Tensile strength and weight per volume are increased by 2 to 5 per cent mica, decrease in strength takes place above 10 per cent. Similar tests were conducted with concrete specimens. Compressive strength is lowered with increasing W/C ratio and decreasing weight per volume. In general, mica has harmful effect on compressive strength and sometimes slightly improving effect on tensile strength. Experiments with iron-mica led to similar results.—A. E. BEITLICH

The rate of calcination of limestone. G. G. FURNAS. *Ind. Eng. Chem.*, May, 1931, V. 23, No. 5, p. 534-8.—Methods and apparatus used in the work are described. Curves are plotted showing relationship between rates of calcination and temperatures. Calcination of limestone takes place in a very narrow zone which is phase boundary between calcium carbonate and calcium oxide. Rate at which this zone advances from outside to inside of piece was constant for any given temperature used. Most of resistance to heat transfer into piece appears to be in narrow zone of calcination, and not in layer of calcined material. A method for determining surface area of particles from calcination data is suggested. The range of particle size used was 2.5 to 8.5 cm. —ROY N. YOUNG

Can by-product carbon dioxide be used in "dry ice" manufacture? D. H. KILLEFER. *Rock Products*, March 28, 1931, V. 34, No. 7, p. 71.—Gases with so low a concentration of CO_2 as those from cement and lime kilns cannot be profitably used at present for making dry ice. Gases from fermentation may be used at cost of removing odors, which is less than cost of removing other gases than CO_2 from usual combustion gases. Gas from coke burned under specially designed boiler has been used, the heat furnishing power to purify and compress about one-third of CO_2 produced.—EDMUND SHAW

PROPERTIES OF CONCRETE

Weather resistance of concrete brick. *Zement* (Germany), April 16, 1931, V. 20, No. 16, p. 375.—To show durability and weather resistance of concrete, a monument is illustrated which was built in 1867 and was awarded

a prize at world's fair in Paris. No visible defects can be detected on this 64 year old structure.—A. E. BEITLICH

The modulus of elasticity for concrete in compression. R. DUTRON. *Summary Reports First I. C. for C. and R. C.*—Modulus of elasticity for concrete is function of its strength, so by implication it depends upon all of factors which affect strength, richness in cement, nature and gauge of inert materials, fluidity, and age of concrete.—LA TECHNIQUE DES TRAVAUX

Study on slow deformations of cement. E. FREYSSINET. *Summary Reports First I. C. for C. and R. C.*—Study of the causes of error; provisional distinction between expansion and shrinkage; results of first series of experiments on rapid variations of shrinkage; variations of shrinkage during periods of long duration; influence of mechanical factors on shrinkage; thermo-hydrometric laws of shrinkage; hydro-elastic laws of shrinkage.—LA TECHNIQUE DES TRAVAUX

The design of the mix and pre-estimation of concrete.—The hardening of cements. L. VANDEPERRE. *Summary Reports First I. C. for C. and R. C.*—Inquiry as to mix of concrete with regard to materials available (cement, ballast or shingle, sand or dust) is based on previous determination of D (maximum diameter of the stones) and d (maximum diameter of the sand or dust). It has long been desired to transform curve of hardening of cements into a straight line by a logarithmic reflection of the values of the ages. In this hypothesis resistance of cement should be taken as increasing continually up to infinite age.—LA TECHNIQUE DES TRAVAUX

Study of the composition of concrete by means of modulus of fineness and of a water cement factor. ANT. BREBERA. *Summary Reports First I. C. for C. and R. C.*—The author considers "The provisional directions for the making of concrete," which he has arranged and which have been approved by the Ministry of Public Works of Czecho-Slovakia. According to these directions determination of best proportion of ballast and of sand is effected by a granulometric analysis on basis of ideal modulus of fineness, which he determines for materials of maximum determined size and by a mixture determined by diagram. Wetting of concrete corresponding to maximum resistance is deduced from author's original diagram.—LA TECHNIQUE DES TRAVAUX

Inert materials and the mechanical properties of concrete. R. DUTRON. *Summary Reports First I. C. for C. and R. C.*—Resistance of concrete to compression, tension, flexure and impact varies—apart from any ot er factor— with nature, shape and gradation of inert materials which constitute its skeleton. It may be stated that, in general, regarding inert materials dealt with in this paper, their order according to effect on compressive strength is almost the reverse of their order according to effect on the other resistances considered. —LA TECHNIQUE DES TRAVAUX

Sins of the concrete fellows. VAN DER KLOES. *Summary Reports First I. C. for C. and R. C.*—Inspection of a silo-building 10 to 12 yrs. old of armed concrete in a deplorable state of deterioration. The author attributes the bad condition to excess water in the concrete mixture, resulting in shrinking and bursting.—LA TECHNIQUE DES TRAVAUX

Mechanical theory of the setting and hardening of cement mortar and concrete. JEAN BASTA. *Summary Reports First I. C. for C. and R. C.*— In this theory, from the results of experimental tests with help of natural laws, are deduced rational equations for the resistance of concrete and also for their use in the calculations for constructions in concrete and reinforced concrete considered from both the static and dynamic points of view.—LA TECHNIQUE DES TRAVAUX

The use of concrete and ferro-concrete in the colonies. C. WOLTERBEEK. *Summary Reports First I. C. for C. and R. C.*—Suitability of concrete for construction in the colonies is discussed. Prevalence of good aggregates,

especially sand is of great importance. It is necessary to design watertight concrete without voids, especially in tropical countries, for great heat and blowing rain have the tendency to deteriorate the alkalinity of the concrete, and this results in a danger of rusting of embedded bars.—LA TECHNIQUE DES TRAVAUX

Light-weight concrete in practice. A. WEISS. *Zement* (Germany), Jan. 29, 1931, V. 20, No. 5, p. 101-5.—In an historical development of reinforced concrete skeleton construction method application of light-weight concrete for such structures is emphasized. Properties of this material are discussed and experiences with various kinds of light-weight concrete are described. Saving of space and high insulating properties are chief advantages.—A. E. BEITLICH

Concrete compressive strength and concrete age. RICHARD FAERBER. *Zement* (Germany), Feb. 19, 1931, V. 20, No. 8, p. 177-8.—A graphical method enables estimates of compressive strength of concrete at later ages. Two curves show relation between strength expressed in per cent of 28-day compressive strength and age in hours (in logarithmic scale) and days. Curves depend upon laboratory test results. Separate curves must be plotted for each individual cement. Method is of value in practice, especially for determination of strength of failed concrete and in cases where existing structures are enlarged or submitted to greater loads.—A. E. BEITLICH

Standard strength and concrete strength. WILHELM STOY. *Zement* (Germany), Feb. 26, 1931, V. 20, No. 9, p. 194-7.—Experiments were undertaken with 10 standard portland cements, 3 high quality portland cements and 3 natural cements to study relations between cement strength and concrete strength with specimens of varying consistency. Results of test support demands that in certain cases properties of cement should also be studied in mixtures of soft and wet consistency (representing better the conditions of practice) besides normal tests with earth-moist consistency. Sand of suitable grain composition should be used for these tests. It is also advisable to use a shaking table of smaller dimensions than asked for in standard specifications.—A. E. BEITLICH

Calculation of heat reactions in winter concreting. MAX MAYER. *Zement* (Germany), April 2, 1931, V. 20, No. 14, p. 322-5.—An empirical calculation method is derived which is based on 4 successive processes in mixing and placing operation of concrete. (1) Sand, gravel, cement and water of temperatures a, b, c and d are mixed and give a concrete of temperature e, (2) Concrete is transported to mold where it arrives with a temperature f, (3) is poured and cools off to temperature g. (4) After several hours concrete will have temperature h. Equations show final temperature of mixture of raw materials calculated from measured temperatures, heat capacities and radiation. Generation of heat in concrete due to chemical reactions of cement is important.—A. E. BEITLICH

About the elastic behavior of concrete with special consideration of diagonal tension. "Uber das elastische Verhalten von Beton mit besonderer Berucksichtigung der Querdehnung." HIROHIKO YOSHIDA. 1930, Julius Springer, Berlin (Germany), R. M. 11:00. Reviewed in *Zement* (Germany), March 12, 1931, V. 20, No. 11, p. 250.—Available information about determination of coefficient of transverse expansion of concrete is greatly enlarged by this book. After discussing previous work, different test methods are characterized such as compressive, tensile and bending test. Results show relations between stresses and elastic behavior of concrete under various loads. Effect of age, W/C ratio, normal compressive strength and cement content are described.—A. E. BEITLICH

New fundamental principles of concrete composition. "Neue Grundlagen der Betonzusammensetzung." OTTOKAR STERN, 1930, Editor: *Ostr. Ingenieur und Architekten Verein*, Vienna (Austria), R. M. 2.00. Reviewed in *Zement* (Germany), April 9, 1931, V. 20, No. 15, p. 352.—Preliminary work of a research program for numerous open questions of influence of aggregates

on quality and economy of concrete, discusses 2 important recent researches: Abrams' fineness modulus and Spindel's constructive concrete calculation. Complicated relations between concrete composition and concrete properties such as consistency, workability, density and strength properties are explained. Final conclusions are based on these theories and their importance for construction practice. Efforts are made to express numerically degree of workability and degree of consistency of concrete.—A. E. BEITLICH

Effect of heating on concrete materials in winter construction jobs. LUZ DAVID. *Zement* (Germany), March 5, 1931, V. 20, No. 10, p. 218-21.—Discussing work done by W. H. Bachelder (cf. *Eng. News-Rec.*, Dec. 18, 1930, p. 973) the author concludes: No objections exist against use of mixing water of temperatures of 140 to 176° F. when materials are mixed in right order. Strength of concrete at about 142° F. decreases only from 20 to 30 per cent. Favorable grain composition and use of high quality cements give in general strengths above specifications.—A. E. BEITLICH

Differentiation of the properties of cements. STIG GIERTZ-HEDSTROEM AND DONOVAN WERNER. *Zement* (Germany), March 5, 1931, V. 20, No. 10, p. 213-5.—After considering major properties of cements such as tensile and compressive strengths, solubility, shrinkage, heat development and setting, authors classify cement into 2 types: (1) Cement for hydraulic structures, which has decreased solubility and small heat development. This cement has probably greater shrinkage, smaller strength properties and slow hardening. (2) Cement for superstructures which hardens more rapidly and shows small shrinkage. It has higher strength, develops more heat and has a greater solubility.—A. E. BEITLICH

A method for the manufacture of concrete with especially high strength. WALTER MARSCHNER. *Zement* (Germany), April 2, 1931. V. 20, No. 14, p. 330.—In connection with a recent German application for patent (No. G 72951) Richard Grün uses as aggregates for manufacture of concrete entirely or partly broken portland cement clinker, high alumina cement clinker or an especially prepared burned material with a relatively high silica content. Compressive and tensile strength are greatly increased and durability in magnesium sulphate solution is considerably improved. Clinker reacts with cement only on its surface and its interior is not attacked even after long exposure to water. Tensile strength increases from 2 to 3 times under normal storage conditions and about 5 times in magnesium sulphate solution; compressive strength is about 3 times higher with addition of these materials than without them.—A. E. BEITLICH

Effect of limestone aggregates on strength of concrete and mortar. P. FILOSSOFOW AND A. SCHTEPETOW. *Zement* (Germany), Feb. 12, 1931, V. 20, No. 7, p. 152-5.—Compressive strength of various concrete mixtures made of high grade aggregates and limestone aggregates with different consistencies were examined. Strength of concrete varied with strength of coarse aggregates. Additions of aggregates of less strength affect strength of rich concrete more than of leaner mixtures. Strength of mortar, which corresponds to a concrete with strong aggregates, is less than strength of these concretes. Strength of mortar, corresponding to concretes with aggregates of less strength, is greater than strength of rich concrete (1:2:4) and less than that of lean mixtures (1:4:8). Poor aggregates affect mortar strength less than concrete strength. In lean mixes mortar strength and concrete strength are similar.—A. E. BEITLICH

Acoustic tests of materials of construction. *Genie Civil* (France), March 7, 1931, No. 10, p. 246-247.—In tests conducted at instigation of Touring Club of France at laboratory of Conservatory of Arts and Crafts, with M. Cellerier in charge, physical and mechanical properties of materials were investigated in their relation to transmission of sound. A distinction is made in acoustic tests between sounds, of given frequency and amplitude, and noises, which are the complex effect of many simple sounds. Readings of the ammeter

of the measuring appratus were recorded for the sound produced: i upon passing through sample section; and I upon direct reception. The ratio of transmitted sound intensity to direct sound intensity was recorded for each material. Parallel tests were made of heat conductivity, permeability, combustibility, hygroscopicity, porosity and strength.—M. A. CORBIN

Modern proportioning of concrete. V. BAEHRNER. *Zement* (Germany), Jan. 22, 1931, V. 20, No. 4, p. 82-4.—Research work in laboratory of Cementa cement plant in Malmo (Sweden) yielded a new concrete proportioning system which takes into consideration quality of cement, consistency of concrete and gradation of aggregates. For calculation of mixture must be known: desired strength of concrete, quality of cement, maximum size of aggregates and desired consistency. With these data and aid of W/C table and proportioning table, can be easily determined proportions of cement, aggregates and water. Water-cement ratio table shows relation between W/C and concrete strength made of cements of different quality. Proportioning table shows relation between W/C, cement-aggregate ratio, amount of cement per unit of volume of concrete and consistency of concrete.—A. E. BEITLICH

How concrete in Wacker Drive attained great strength. *Concrete* April, 1931, V. 38, No. 4, p. 15-16.—Strength of 11,400 lb. was attained in Wacker Drive concrete, Chicago, due to complete hydration of cement particles. Process of hydration is best understood if fineness, or size distribution, of cement is considered, particularly with respect to quantity of fine sizes present. Length of time required for hydration is shortened as size of cement particles decreases. Ordinarily in building construction work, only three of fine sizes, representing about 45 per cent of quantity of cement, have time to become completely hydrated during short curing period and before remaining water is dried out. Three larger sizes, or 55 per cent of total quantity are never hydrated. In outdoor concrete, subsequent periods of rainy weather supply moisture that causes resumption of hydration of coarser particles and eventually all cement becomes hydrated and further strength is attained. Higher early strength is obtained with ordinary portland cement, partly by greater fineness and increasing percentage of smaller particles.—C. BACHMANN

Researches in concrete aid the engineer. H. F. GONNERMAN. *Civil Engineering*, May, 1931, V. 1, No. 8, p. 727-732.—Reinforced concrete construction was first proposed about 70 years ago by E. Coignet, a French engineer, and first investigations were made from 1870 to 1880 by an American engineer, Thaddeus Hyatt. From 1880 to 1900 important contributions to knowledge of subject were made by Feret, Considere, Monier, Hennelbique, Christophe, Bauschinger, Tetmajer, Bach, Martens, Morsch and others. During the period 1900 to 1914 American investigators, Talbot, Hatt, Humphrey, Turneaure and Withey reported numerous researches but properties of plain concrete were given relatively little attention. Agencies now engaged in study of concrete and related materials include national technical organizations, government bureaus, industrial organizations, and colleges. One interesting investigation consists of a study of the behavior of a variety of concrete structures over a wide range of climatic exposures and particularly those in direct contact with water. Observations indicate principal destructive agents are repeated freezing and thawing of saturated, porous concrete and solvent action of water finding its way through porous concrete mass.—D. E. LARSON

Some notes on proportioning concrete. HAROLD JAMES VOGAN. *Trans. Institution Engineers Australia*, V. 12, 1931, p. 1-15.—Concrete specifications of 1920 and 1929 are compared and revolutionary changes in design of mixes discussed, with comprehensive resume of theories for concrete design. The author points out the great value of fundamental work by Feret on mortar mixes in 1892. Fuller's mechanical analysis method, Abrams' water-cement ratio method and McMillan's recent work are reviewed. The value and significance of Power's and Edwards' contributions have not been overlooked. The results of work of Talbot and Richart in 1923, which contains investigations of funda-

mental importance, enables correct interpretation of results of other investigators. General comparison of methods and theories reveals agreement by investigators on fundamentals not apparent upon casual examination. These findings included: Importance of voids in concrete or mortar and percentage of cement; that strength and density of concrete are affected by variation in size of sand particles more than by variation in stone particles. None of the experimenters showed any advantage gained from sand with sharp grains. Tests bearing on these theories have been conducted at Peter Nicol Russell School of Engineering, University of Sydney. Comparison of actual and calculated values of W/C shows differences ranging from +1% to +12% and from -7% to -34%. More experiments are in progress.—N. H. ROY

Basic principles of concrete making. F. R. MCMILLAN. *Civil Engineering*, April, 1931, V. 1, No. 7, p. 601-606.—When aggregate in concrete is completely surrounded by cement-water paste, forming a uniform and homogeneous mass, properties of the concrete are principally determined by the properties of the hardened paste. In some cases, the properties of concrete are greatly affected by certain characteristics of the aggregate, but this does not reduce the importance of the paste for, regardless of kind or combination of aggregate, any change in properties of paste will at once be reflected in character of concrete. Chemical reactions responsible for setting and hardening which transform plastic cement-water paste into hard binding medium are termed hydrolysis and hydration. Curing conditions required for completion of these reactions are time, favorable temperature, and continued presence of water. Hydration is essentially complete at from 6 to 12 months both for standard portland cements and for high early strength cements. Strengths are correspondingly lower for shorter periods. Factors affecting these strengths are: relative proportions of cement and water, or w/c ratio; completeness of chemical combination between cement and water, that is, curing; characteristics of cement. These three factors also determine other qualities of the hardened paste such as watertightness and durability. In general, watertightness is a function of w/c ratio, time and rate of hardening just as compressive strength is a function of same factors. Principal disintegrating agencies are repeated freezing and thawing and action of percolating water.—D. E. LARSON.

Aggregates and the physical properties of concretes. (See MATERIALS —AGGREGATES.)

ENGINEERING DESIGN

BRIDGES

The bridge of Prince Joseph Poniatowski over the Vistula in Warsaw. B. PLEBINSKI. *Summary Reports First I. C. for C. and R. C.*—This bridge is known in Polish history of bridge construction not only as the largest bridge in Poland, 9840 ft. long (including the viaducts), but chiefly because for the first time concrete has been used on a large scale for its construction together with iron and steel.—LA TECHNIQUE DES TRAVAUX

Railway underbridges of concrete and reinforced concrete in Spain. J. EUGENE RIBERA. *Summary Reports First I. C. for C. and R. C.*—Note contains complete information on very large number of underbridges in concrete and reinforced concrete constructed in Spain in a period of over 20 years, with drawings of bridges of Torre Montalvo (concrete arches of 100 ft.) and straight bays at a sharp skew with a wide span of 65 ft. for the transpyrenean railway from Lerida to Saint-Girons.—LE TECHNIQUE TRAVAUX

Reinforced concrete in engineering. M. GERARD. *Summary Reports First I. C. for C. and R. C.*—Author deals briefly with some classes of engineering structures to which reinforced concrete has been applied in Great Britain. First among these are bridges, of which many hundreds have been built on the Hennebique system since the year 1900. Three improvements in jetty, pier

and quay construction introduced by Mouchel and his successors are dealt with in the succeeding section of report.—LA TECHNIQUE DES TRAVAUX

Test measurements on the Arlington Memorial bridge at Washington, D. C. J. FISHBURN. *Summary Reports First I. C. for C. and R. C.*—The Arlington Memorial Bridge Commission and the National Bureau of Standards of the United States Department of Commerce are jointly conducting a series of tests on the Arlington Memorial bridge, across the Potomac River at Washington, D. C. to obtain data on structural behavior of one of arch spans. The paper discusses principally design and construction of instruments used and accuracy of data obtained. Change in bending strain at points along the arch extrados, which occurred between adjacent tests is shown as computed from the test data.—LA TECHNIQUE DES TRAVAUX

The possibility of substitution of concrete arches over very large spans for metallic structures of all kinds. E. FREYSSINET. *Summary Reports First I. C. for C. and R. C.*—First part, study of possibilities arising from properties of materials. Second part, choice of forms of structures. Third part, methods of carrying out work.—LA TECHNIQUE DES TRAVAUX

Note on arched bridges in Switzerland. R. MAILLART. *Summary Reports First I. C. for C. and R. C.*—As regards Switzerland the picture is completed by several works of native conception absolutely free of foreign influence. Whilst greater part of these have been described, principally in *Schweizerische Bauzeitung*, and in the Reinforced Concrete Handbook of Emperger, a new process of arch construction has been described in detail as particulars have not previously been published.—LA TECHNIQUE DES TRAVAUX

Recent developments in arch design. W. L. SCOTT. *Concrete Constr. Eng.* (England), March, 1931, V. 26, No. 3, p. 180-187.—Increase in spans of reinforced concrete bridges during recent years has led to investigation of variable factors which, in past have been ignored or assumed to vary in a manner amenable to straightforward mathematical treatment. Assumptions for moderate span bridges, up to 150 ft., are not sufficient for spans of several hundred feet. Approximate assumptions have been made to standardize influence lines. Principal assumption consists in considering axis of arch to coincide with line of resistance from total dead load and to be a parabola of second degree. This is only true for uniform dead load and for large spans. Error due to this assumption cannot be disregarded especially for arches of the solid spandrel type. Another assumption is that variation in the moment of inertia due to diminishing depth of arch towards the crown varies according to value $I = I_c / \cos \alpha$, where I_c = cross sectional inertia at crown and α = angle of inclination of arch ribs with horizontal. These two assumptions are permissible for moderate spans. However total dead load is not uniform, variation being greater with solid spandrel than open spandrel type arch bridges. Hence instead of taking the curve of the arch axis to be a "square" parabola it is necessary to find curve that will coincide with line of pressure for loading, part of which is uniform and part variable. Further refinement of arch curve is to consider bridge loaded with one-half of average distributed superimposed loading and to make arch axis curve fit this condition. This curve will be a parabola of the fourth degree and may be expressed as follows: $\frac{y}{f} = 1 - (1 - k)\, m^2 - km^4$ where y = vertical ordinate of any section to mean fibre above springing level, f = rise of arch above springing level, m = horizontal distance of sections from the center line of the arch in terms of the half span, and k = a constant depending on the load variation. For economical variation in moment of inertia it is found by practice that suitable depth at springing is about 1½ times that at crown, corresponding moment of inertia is about 3½ times that at crown. With object of standardizing the investigation following expression for inertia variation is given: $I = I_c / \cos \alpha\ (1 - 0.7m^4)$. Maximum negative and positive moment at a section are obtained

from influence lines using ½ calculated superload as covering entire bridge. Secondary thrust is permanently eccentric producing shortening and hence flattening of arch. Arch shortening is produced also by shrinkage of concrete, displacement of abutments, and drop in temperature. Two devices are used to eliminate secondary effects: temporary hinges or hydraulic jacks to open arch at crown.—J. MARIN

The strengthening of metallic latt.ces by reinforced concrete. FR. EMPERGER. *Summary Reports First I. C. for C. and R. C.*—Strengthening of metallic lattices is so carried out that compressed bars are covered with bound concrete and tension bars are reinforced by additional bars welded at their ends to lattice framework. The method is explained with aid of example of a cantilever girder with a central span of 36.0 metres.—LA TECHNIQUE DES TRAVAUX

Fundamental data for the calculation of solid bridges. "Berechnungsgrundlagen fur massive Brucken." 1930, Wilhelm Ernst and Son, Berlin (Germany), R. M. 1.50. Reviewed in *Zement* (Germany), March 12, 1931, V. 20, No. 11, p. 250.—Book contains a list of all necessary data in concise form for design of solid bridges. Special consideration is given to German standard specification.—A. E. BEITLICH

Bridge piers in Suisan Bay supply test of concreting methods. C. R. HARDING. *Concrete*, April, 1931, V. 38, No. 4, p. 9-11.—Bridge of Southern Pacific Ry., has a total length of 5603 ft. and comprises numerous spans of steel construction, to support which, concrete substructures were built with bases resting upon solid rock. These abutments and piers were designed to carry their own weight, that of the substructure and certain specified engine and train loads, critical combinations were made of maximum live-load reactions, total dead load of superstructure and substructure with and without allowance for bouyancy, together with overturning effects of wind pressure, acting longitudinally, and transversely on spans and piers, horizontal tractive forces from stopping and starting trains, and horizontal forces against piers from wave action and pressure from stream currents. To prevent shattering of the concrete by earthquake tremors, the main piers were heavily reinforced. —N. H. ROY

Design of a bridge over Lake Maeler in Stockholm (Sweden). RICHARD FAERBER. *Zement* (Germany), Jan. 29, 1931, V. 20, No. 5, p. 105-9.—Bridge design by Faerber and Schuhmacher, submitted to international contest (cf. *Zement* (Germany), July 1930, V. 19, No. 30, p. 712-4; *Journal A. C. I.*, Oct., 1930, V. 2, No. 2, *Abstr.* p. 39) embodies unique features. Use of rammed concrete is proposed. Design of 2 dissimilar arches was necessary on account of location of suitable sound rock for foundation of river pier. Spans of arches are 738.2 and 524.9 ft. and their heights are 74.1 and 66.9 ft. These are record dimensions for this type of bridge. Arches are 7.2 ft. thick at center and 12.1 ft. at abutments. Total width of bridge is 80.7 ft. Greatest stability and durability and smallest costs of upkeep were demanded. Arches are designed in 3 parallel strips to reduce costs of centerings. Detail are given of calculation of stresses and deformations of structure. Mixing devices are provided with automatic measuring equipment for water. Concrete is to be rammed by means of compressed air to increase strength and uniformity. Roadway consists of a number of similar slab sections, which rest on 4 horizontal beams, supported by 2 transverse beams.—A. E. BEITLICH

Method of arch design. G. P. MANNING. *Concrete Construction Eng.* (England), April, 1931, V. 26, No. 4, p. 250-53.—By using "ready made" influence lines labor of preliminary arch designs and estimates is reduced and errors eliminated. If abutments are expensive, open-spandrel arch is selected; if head room is insufficient ribs may be carried up through deck. For open-spandrels, spacing of ribs is next decided and deck designed. Two profiles are selected as being generally useful as first assumption. Influence lines are

obtained from tables given also maximum moments, thrusts, and shears for all sections of arch rib. Best shape of arch is determined from loads and working stresses for each particular case.—JOSEPH MARIN

A concrete arch of 460-ft. span. G. S. RICHARDSON. *Eng. News Record*, Apr. 23, 1931, V. 106, No. 17, p. 680-683.—The largest concrete bridge project yet planned by Allegheny County involves 1,500 ft. of high-level structure over Turtle Creek Valley and includes five reinforced concrete arches, one of which is 460 ft. long between pier centers. All piers and abutments are founded on solid rock. Each span has two arch ribs 14 ft. wide. Deep ribs were avoided on account of temperature and rib shortening stresses. All ribs are designed for maximum working stress of 800 lb. per sq. in. under combined dead load, live and impact load, rib-shortening and temperature stresses, this working stress being based on minimum 2000-lb. concrete. Temperature stresses are calculated for drop of 40 deg. and rise of 20 deg. F. Columns on the ribs are arranged in pairs so that, in cross-section, each bent forms a four-legged rigid frame with adequate lateral stiffness to tie two ribs together. Expansion joints are provided at the ends of span only.—D. E. LARSON

The contest for the Dreirosen bridge in Basel (Switzerland). *Zement* (Germany), March 26, 1931, V. 20, No. 13, p. 298-302.—In addition to description of bridges given by Berger (cf. *Zement* (Germany), Jan. 15, 1931, V. 20, No. 3, p. 59-61; *Journal A. C. I.*, April 1931, V. 2, No. 8, *Abstracts*, p. 223), two designs, awarded prices, are illustrated. (1) Continuous reinforced concrete beam with one fixed end at shore abutment and movable bearings at other supports. Bridge has 4 openings and rests on 2 river piers and 1 shore pier. Caisson method is proposed for placing of river piers. Calculation of stresses is given as well as exact data concerning excavating, proportioning of concrete and arrangement of mixing plant and transportation of concrete at site of construction. (2) Three-hinged reinforced concrete frame structure has 3 openings, 161.4, 331.4 and 161.4 ft. wide. Cross-section of 3 hollow beams which support roadway have interesting design. Roadway consists of cross-reinforced slab 8 in. thick. River pier foundations are caissons.—A. E. BEITLICH

The Echelsbach bridge. A Melan-arch with longest span. "Die Echelsbacher Brucke. Der weitestgespannte Melanbogen." F. DULL AND R. GERHART, 1931, Wilhelm Ernst und Sohn, Berlin (Germany), 76 p., 88 illustrations, R. M. 8.40. Reviewed in *Bautechnik* (Germany), March 20, 1931, V. 9, No. 13, p. 191.—A very complete picture of outstanding reinforced concrete arch bridge, great span of which was built without any centerings, is presented and various designs are discussed. Every phase of construction program is described in all details. Arrangement of site of construction, concrete mixing plant and transportation of structural materials are illustrated. Static calculations are given in full.—A. E. BEITLICH

Laboratory tests of reinforced concrete arches with decks. WILBUR M. WILSON. *U. of I. Eng. Exp. Sta. Bulletin* No. 226. April, 1931.—Eight reinforced concrete arches of 17 ft. 6 in. span and 4 ft. rise were tested to destruction. Two specimens were composed of ribs only. Two had rectangular deck slab supported on columns well above crown of arch, and had no expansion joints. Two had T-shaped deck slab supported on columns well above crown, one of these having expansion joints at third points. Two had T-shaped deck slab placed low and built monolithic with rib at crown, one of these having expansion joints at third points. All specimens were subjected to same distribution and intensity of loading (to failure) with greater intensity on one side of the center than on the other. Strains were measured on both concrete and reinforcing. Celluloid models of the experimental arches, and of other arches having various geometrical properties, were tested. Conclusions from this investigation are: Deck and arch rib act together structurally and analysis should be made on this basis for any important structure; expansion joints reduce the strengtening effect of the deck; when the deck is placed high above the rib at center (generally an unwarranted arrangement) expansion

joints may be necessary in medium and long spans; when vertical clearance is large it will generally be advantageous to increase rise of rib and place deck low with respect to rib.—ARTHUR R. LORD

Concrete trusses and 47-ft. slabs in new Seattle viaduct. CLARK H. ELDRIDGE, *Eng. News Record*, April 16, 1931, V. 106, No. 16, p. 642-644. Distinguishing features of reinforced-concrete design, of West Garfield St. bridge, recently completed in Seattle include heavy flat slab construction on spans up to 47 ft. and reinforced concrete trusses 60 ft. long. The structure is 3,010 ft. long between abutments. Design specifications were based on a live load of two 20-ton trucks with 100 per cent impact allowance on rear axle of one truck. A concrete mix of approximately 1:2:3, developing 3000 lb. per sq. in. in 28 days, was specified, and a working stress of 1,200 lb. per sq. in. used in design. The one-way slab section of bridge consists of bents of two or more columns capped with wide shallow beams. A heavy slab, reinforced primarily in one direction and thickened for negative moment at supports, spans directly from bent to bent, without beams or girders. Advantages of this type of construction include: simple formwork; large and unerowded reinforcing bars; use of concrete of low water content; thorough curing; maximum clearance; distribution of heavy wheel loads; low cost. Reinforced concrete trusses have 60-ft. spans with 15-ft. cantilever panels at both ends. A 13-ft. suspended slab spans between cantilever ends of adjacent trusses. Lower chords and tension diagonals of truss consist of flat structural-steel bars connecting with ends of compression members by curved plates that loop around and engage concrete. These flat bars are wrapped with wire mesh and concrete is poured around the assembly.—D. E. LARSON

BUILDINGS

Applications of reinforced concrete in building construction. A. LOPEZ-FRANCO. *Summary Reports First I. C. for C. and R. C.*—A summary of the works of this kind planned or carried out by authors snce 1910 in which they began to practice in this speciality, omitting details of procedure and design.—LA TECHNIQUE DES TRAVAUX

Roof of thin reinforced concrete slabs.—System Zeiss-Dywidag. FR. DISCHINGER. *Summary Reports First I. C. for C. and R. C.*—Author gives complete description of development of roof of thin reinforced concrete slabs of Zeiss-Dywidag system, which are known by monumental structures of covered halls of Frankfort and Leipzig. He examines the possibilities of further developments.—LA TECHNIQUE DES TRAVAUX

Spacious reinforced concrete hangar for the Seville airport. A. PENA BOEUF. *Summary Reports First I. C. for C. and R. C.*—This hangar is destined to hold two Zeppelin type airships. It is designed to be built of reinforced concrete, forming a series of parabolic arches, the centre of gravity of which lies on the directrix of main arch which is in shape of a normal catenary. It is calculated for the fundamental effects: dead weight, force of wind and thermic effect, and two hypotheses have been taken, corresponding to the thrust of the outer air and the simultaneous thrust of interior.—LA TECHNIQUE TRAVAUX

State hospital for children in Bern (Switzerland). F. HILLER. *Schweizerische Bauzeitung* (Switzerland), Jan. 3, 1931, V. 97, No. 1, p. 3-6.—Modern hospital was erected in reinforced concrete skeleton type. All floors, except cantilevered rest room floors, were built as supportless hollow brick structures. Floors of rest rooms were made of solid reinforced concrete. Visible expansion joints allow for shrinkage of concrete.—A. E. BEITLICH

Concrete mill design governed by machinery layout. EDMUND WILKES, JR., *Eng. News Record*, Apr. 2, 1931, V. 106, No. 14, p. 561-564.—Plant of the Ralston-Purina Co., at Denver, Colo., offers an interesting example how predetermined machinery layouts may affect reinforced concrete design.

Three main units of plant incorporated in a single structure are (1) a grain elevator headhouse 56 x 76 ft. in plan and 112 ft. high, surmounted by a cupola 74 ft. high; (2) a battery of fifteen grain tanks 18 ft. in diameter and 89 ft. high; (3) a feed mill 52 x 180 ft. in plan and eight stories high. Feed mill building contains five groups of rectangular bins nearly all of which are two stories deep. Bin locations were fixed by machinery layout and could not be shifted to accommodate structural design. Room for beams underneath bin walls was not available so the walls were made self supporting and concrete floors were suspended from them. Columns, beams and walls in bin area were constructed of reinforced concrete poured in continuous vertical run using sliding forms. Pockets were left in columns and walls to support floors, which were designed as two-way slabs supported by beams in both directions with exception of those supported from walls.—D. E. LARSON

Results of measurements of deformations and stresses of mushroom slabs. M. ROS AND A. EICHINGER, *First I. C. for C. and R. C.*, Liege, Sept., 1930.—Tests were made on six different mushroom slabs having square panels. Results of measurements of stresses, for Poisson's ratio $m = \infty$ and $m = 6$, and deflections are summarized for two buildings as follows: (1) Maximum moments in middle of panel, or half way between two columns are not essentially different from one another for loads uniformly distributed in a series of panels in line. (2) Points of inflection of elastic curve, for plane passing through axis of columns, i. e., the points where moment is zero, are from $0.22L$ to $0.28L$ distant from the axis of columns. (3) Bending moment of columns below and above slab (M_o and M_u), the latter having load uniformly distributed in a series of panels in line, permit: $M = M_o + M_u = \frac{pl^3}{16.8}$. M should be distributed on the two columns. For unusually strong columns and for considerably developed mushrooms, bending moment which obtains at two columns, reaches a value perceptibly higher, and may even exceed the value, corresponding to entirely built-in or fixed condition, $M = \frac{pl^3}{12}$. Maillart in 1908 found the following: for uniform load in panel of mushroom slab considered, calculated according to surface of deflection, in middle of panel, $M = \frac{Pl^2}{37}$, halfway between two columns, $M = \frac{Pl^2}{22}$. On two different mushroom slabs with ratio of length to breadth 1.8:10, results summarized are: (1) Bending moments in middle of panel and half way between two columns are equal for a load uniformly distributed in a series of panels in line (with longer sides adjacent) (2) Calculation by method of substitute or auxiliary frame gives values in close agreement with values obtained by measurements, for: positive moments in middle of a panel and halfway between two columns; negative moments at built-in or fixed point; bending moments of columns; and for deflections.—R. B. B. MOORMAN

DAMS

Hydro-electric plant at Porjus, Sweden. GEORGE WILLOCK. *Canadian Engineer*, Jan. 27, 1931, V. 60, No. 4, p. 9.—Hydro electric power plant, run and owned by Royal Board of Water Falls, Sweden, most northerly power plant in the world, has dam 4100 ft. long consisting of three parts, one portion forming the intake. To reduce ice pressure upstream faces are given a gradual slope with piers, walls, crest and downstream sides of spillways protected by a stone coating anchored to concrete foundations. The intake structure is of solid concrete.—G. M. WILLIAMS

Honeycomb gravity-type concrete dams. C. E. GRUNSKY. *Civil Engineering*, April, 1930, V. 1, No. 7, p. 630-631.—A new type of concrete gravity dam having galleries for cooling and draining the interior is suggested

by author. There is tendency for temperature in interior of massive concrete structures to rise for some time after concrete has been placed. To simplify the high gravity dam, it should be straight, not arched; to take advantage of water pressure, treated as load, its upstream face should be inclined; to prevent cracking there should be both horizontal and vertical joints, not too far apart; to keep water from permeating concrete and reaching joints and cracks where its presence under pressure would be undesirable, masonry near upstream face should be thoroughly drained, or a metal diaphragm should be provided. Any part of dam above an assumed horizontal plane at any elevation should be planned to satisfy the requirements of a dam with its base at level of assumed plane. The new dam suggested by author has an inclined upstream face with an imbedded metal membrane to prevent penetration of water. Fair-sized galleries, open at the downstream face, are provided both to cool the interior and reduce the weight of masonry. Vertical joints are carried from top of dam to foundation.—D. E. LARSON.

MISCELLANEOUS

The largest reinforced concrete syphons in the world. J. EUGENE RIBERA. *Summary Reports First I. C. for C. and R. C.*—Siphon of Sosa is formed of two tubes 3350 ft. long and 12.5 ft. in diameter; that of Albelda of a tube 2360 ft. long and 13.1 ft. in diameter. Both constant head of 85 and 98.5 ft. and for more than 20 years are of normal service to irrigate 247,000 acres in Aragon and Catalonia.—LA TECHNIQUE DES TRAVAUX

Reinforced concrete construction in Poland. W. PASZKOWSKI. *Summary Reports First I. C. for C. and R. C.*—Conditions in Poland have favored use and development of reinforced concrete from its introduction, the country being rich in raw materials required for making portland cement and in all kinds of stony materials suitable for concrete.—LA TECHNIQUE TRAVAUX

Progress of reinforced concrete construction in Germany. W. PETRY. *Summary Reports First I. C. for C. and R. C.*—The basis of the constructive design and carrying out of works in reinforced concrete is governed by official regulations, at the moment in process of revision. Working loads depend on execution and the supervision. The conditions of a good execution will be assured and increased by the directions of control of German Association of Reinforced Concrete.—LA TECHNIQUE DES TRAVAUX

Tests on the hooked ends of reinforcing bars. TH. WYSS. *Summary Reports First I. C. for C. and R. C.*—Question of maximum curvature permissible for anchorage hooks is discussed on basis of recent experiments on forming of steel reinforcement.—LA TECHNIQUE DES TRAVAUX

Railway sleepers in reinforced concrete. FR. EMPERGER. *Summary Reports First I. C. for C. and R. C.*—Two slabs (blocks) and a junction piece are assembled in position for a single sleeper. Slabs are of a form appropriate to their use and suitable for bearing on ballast. A complete comparison is made with usual systems of reinforced concrete sleepers in use on the Hungarian and French railways.—LA TECHNIQUE DES TRAVAUX

Theorical and experimental study of the load capacity of concrete piles.—Concrete piles with enlarged base. J. SPRENGER. *Summary Reports First I. C. for C. and R. C.*—The "reinforced concrete pile with enlarged base," an invention of the author, proved to have larger resistance at base than an ordinary concrete pile. For this reason an increase of 50 per cent to the allowable load seems to be correct. A formula for reinforced concrete piles is deducted.—LA TECHNIQUE DES TRAVAUX

The crippling of rectilinear members of eccentric loads. M. R. CHAMBAUD. *Summary Reports First I. C. for C. and R. C.*—The analysis of Euler which determines exactly the critical crippling load for axial loading cannot be extended to crippling by eccentric loading, and attempts made in this direction have tended to some extent to falsify ideas on the true nature of

the phenomenon. Present memoire presents an exact theory of eccentric crippling based on complete equations of bending and properties of elliptic functions.—LA TECHNIQUE DES TRAVAUX

Calculation of columns of reinforced concrete with spiral reinforcement. J. PODOLSKY. *Summary Reports First I. C. for C. and R. C.*—In the calculation for buckling of reinforced concrete columns with spiral reinforcement, limit of the resistance of the concrete is determined by formula of M. Navier. We can find by two methods the radius of inertia (radius of gyration) of section of columns reduced to the form of concrete. We can determine this radius of inertia. The two methods give satisfactory results.—LA TECHNIQUE DES TRAVAUX

Experimental research with influence lines relative to plane rigid constructions. G. MAGNEL. *Summary Reports First I. C. for C. and R. C.*—Structures in reinforced concrete present numerous problems in the solution of rigid systems. The most perfect systems of calculations are based on a series of simplifying hypothesis. Author's microinfluentiometer permits formation on celluloid models of influence lines of rigid elements with a maximum error of 2 per cent.—LA TECHNIQUE DES TRAVAUX

Calculation of combined bending, (bending and tension) by the aid of a new rule adapted from the logarithmic system of Rieger for the calculation of combined bending (bending and compression) by the aid of 3rd rule adapted to the rule of Rieger. J. RIEGER. *Summary Reports First I. C. for C. and R. C.*—The author has found it necessary to complete his rule by a fourth rule for the calculation of eccentric tension. The disposition of this rule is analogous to that of the 3rd rule.—LA TECHNIQUE DES TRAVAUX

Report on plane bending. JOHN SOUBRE. *Summary Reports First I. C. for C. and R. C.*—Author has deliberately confined his work to case in which section is subjected to compression throughout its extent. Taking as a point of reference the neutral axis and not centre of gravity of imaginary section, he states the various equations of equilibrium and derives from them a series of formulae which constitute an easy method of calculation applicable to various problems met with in current practice.—LA TECHNIQUE DES TRAVAUX

The mean fibre of large rigid arches. F. CAMPUS. *Summary Reports First I. C. for C. and R. C.*—By reason of permanent, elastic and reversible shortenings of large rigid arches, the funicular polygon of fixed loads does not constitute most favorable forms of mean fibre of these structures. A direct simple method of correction is deduced from the ingenious conception of Prof. E. Timochenko, which consists of calculating hyperstatic arches, of which the mean fibre coincides with the funicular polygon of the loads or is very near to it, by taking as a basic isostatic system the three hinged arches.—LA TECHNIQUE DES TRAVAUX

Experiments of the form of lines of principal stress in problems of two dimensions. AUGUSTE MESNAGER. *Summary Reports First I. C. for C. and R. C.*—It is known that in two dimensions lines of principal stress form two families of orthogonal curves which are perpendicular or tangent to contours, and that resultant angles form single points of first order and salient angles of second. By superimposing the two solutions we obtain forms relative to problems of St. Venant for girders loaded at one point.—LA TECHNIQUE DES TRAVAUX

Calculation of relatively thin annular sections uniformly reinforced on their circumference and stressed by plane bending and direct load. LOUIS BAES, LUCIEN VANDEPERRE AND JACQUES VERDEYEN. *Summary Reports First I. C. for C. and R. C.*—The problem of annular sections of this type is chiefly met in pylons or posts and chimneys in reinforced concrete. The authors have made the graphs which form the subject of the note in connection

with an expert investigation for a chimney of reinforced concrete.—LA TECHNIQUE DES TRAVAUX

Calculation of straight members of rectangular section doubly reinforced and stressed by plane bending and direct load. LOUIS BAES AND LUCIEN VANDEPERRE. *Summary Reports First I. C. for C. and R. C.*—The note presents two types of solutions by graphs. The first consists of a series of five graphs of which one only is given.—LA TECHNIQUE DES TRAVAUX

Examples of the construction statics. "Ubungsaufgaben aus der Baustatik." RICHARD LINDT, 1930, Max Jänecke, Leipzig (Germany), Part 1 and 2, RM. 3.00. Reviewed in *Bautechnik* (Germany), March 20, 1931, V. 9, No. 13, p. 195.—More than 540 examples from all fields of statics are given. They deal with composition and separation of forces, determination of loads and stresses in structural members, calculation of beams and columns, strength, wind pressure, water pressure and earth pressure. Laws of statics are illustrated.—A. E. BEITLICH

Symmetrically reinforced sections under eccentric loads. A. PUCHER. *Beton u. Eisen* (Germany), April 20, 1931, V. 30, Heft 8, p. 156-158.—In consideration of concrete stresses in extreme fibres of rectangular and ring sections eccentrically loaded, concrete symbols are substituted into formula for stress due to axial load combined with bending and an expression is obtained for the ratio of max. and the min, f_c to the average f_c in terms of properties of section, eccentricity, constant n (15 is used), and steel ratio. This expression is for construction of charts giving for various eccentricities and steel ratios the ratio of max. and min. f_c to average f_c. Chart for rectangular sections covers a range of (total) p values up to 6 per cent and eccentricities up to 0.35. Chart for ring sections includes sections varying from thin shelled cylinders (shell thickness equal to 0.025 of outside diameter) to solid sections. Charts are constructed on assumption that concrete takes tension and that n equals 15.—A. A. BRIELMAIER

Economic design of reinforced concrete piles. J. P. PORTER. *Concrete Constr. Eng.* (England), March, 1931, V. 26, No. 3, p. 202-210.—Greater economy in design of concrete piles is permitted because of development in strength of cement, introduction of rapid-hardening cement, greater care taken in making concrete and information on bearing values of piles. Factor of safety is determined based upon: quality of material passed through, ratio between bearing and frictional support, ratio between dead and live load and possibility of frictional support being increased by re-settlement of the ground. Second step is to determine dimensions and arrangement of the piles to be used. Considerations in designing a series of piles are: quality of concrete, stresses to be used, bending moments during handling, safe short-column length of pile and probable ground resistance. Allowable stress of 18,000 lb. per sq. in. in steel is proposed. Table given of allowable compressive strengths of concrete of different grades for a factor of safety of 3 and value of modulus ratio $m = 15$, 12, 10, and 8 for the different grades of concrete considered. Allowable stresses in shear for concrete is based on assumption of Navier's theory of failure. Attempt is made to treat subject of lateral reinforcement theoretically rather than empirically.—J. MARIN

The economic design of reinforced concrete piles. J. P. PORTER. *Concrete Constr. Eng.* (England), April, 1931, V. 26, No. 4, p. 236-44.—Loads and forces sustained by piles are: (1) bending and shear stresses while being handled, (2) compression, shear, and possibly buckling crushing stresses while being driven—in body of pile, (3) crushing stresses while being driven—in head and foot of pile, and (4) compression, shear and possibly buckling stresses under working load. Reinforcement of 2 and 4 per cent is selected. Expressions are given for maximum moments produced for specified types of slings, and for maximum length of piles in terms of resisting moment and cross section. Approximate relation is obtained for resisting moment in terms of

cross-sectional dimensions of pile, area of steel, distance of steel from edge and distance of neutral axis from outer fibre. Shear strength for long piles is supplied by links. Relation is deduced for shear assuming pile supported at one end and at quarter point. Shear steel is necessary to resist impact stresses, to give resilience, to resist bursting pressure of concrete and to prevent buckling. Quantity of shear steel should be at least doubled for the first 2 or 3 ft. at head and foot of pile. Pile is assumed as "short column" if hammer blow is axial and if equivalent "unsupported" length does not exceed 15 times core width. In selection of piles, number and spacing to be used is determined and working load per pile derived. Ultimate ground resistance to which pile is to be driven is determined. If "short column action" only is the condition, a suitable pile can be selected from table. If "long column action" is likely, ultimate ground resistance is multiplied by a reduction factor to determine the safe "short column" load.—JOSEPH MARIN

Modern reinforced concrete structures of special designs. WILHELM PETRY. *Zement* (Germany), Feb. 12, 1931, V. 20, No. 7-8, p. 149-52, 170-4.—Recently completed reinforced concrete structures of special interest on account of peculiarities in their design and construction include: Retaining wall at sand beach in Wannsee (Germany); reinforced concrete tunnel for bituminous coal mine in Finkenheerd which was constructed over railroad of mine, under considerable difficulties; foundation of a traveling coal unloading crane on Teltow channel; Several loading platforms for sand, lime-stone for new cement plant in Neuwied (Germany), coal and aggregates.—A. E. BEITLICH

The rational reinforcement of concrete. *Engineering* (England), March 27, 1931, V. 131, No. 3402, p. 409.—Distribution and arrangement of steel in secondary reinforcement to resist shearing stresses should provide for its disposal along tension lines of principal stress. Use of stirrups perpendicular to neutral axis of beam is uneconomical since principal stresses cut neutral axis at angle of 45 deg. Main reinforcing bars not needed for tension should never terminate parallel with the upper surface of beam but should first be turned at an angle of 45 deg. to neutral axis, and then bent round further so as to end at right angles to upper surface. Any shear can be resolved into a tension and a compression at right angles to each other. From symmetry best arrangement of metal to take tensions will be to place it at right angles with line of thrust. Hence in reinforced concrete truss steel work should be arranged horizontally in tension members and at right angles to axis of struts. In case of bow string girders these members are subject to bending moment as well as direct thrust or pulls and reinforcement should be given a corresponding curvature, meeting compression face perpendicularly but tension side at angle of 45 deg.—G. M. WILLIAMS

Report of the 33rd main meeting of the German Concrete Association on March 17, 18 and 19, 1930. "Bericht uber die 33ste Hauptversammlung des deutschen Beton-Vereins am 17., 18. und 19. Marz 1930." 510 pages with numerous illustrations and tables. Reviewed in *Bautechnik* (Germany), March 20, 1931, V. 9, No. 13, p. 193.—Book contains complete text of 15 papers presented at this meeting and gives a review of newest developments in reinforced concrete practice and its many applications. Descriptions of outstanding structures, mostly erected in Germany, and theoretical discussions are included.—A. E. BEITLICH

Load members. "Belastungsglieder. "A. KLEINLOGEL, 1931, Wilhelm Ernst und Sohn, Berlin (Germany), 4th edition, 117 pp., 127 illustrations, 32 tables, RM. 9.00. Reviewed in *Bautechnik* (Germany), March 20, 1931, V. 9, No. 13, p. 192.—This is a supplement to several books by same author. Besides load members it discusses all static values, moments and transverse stresses. Formulas and equations are presented in simple and clear manner. Main chapter deals with stresses and moments of simple beam for single loads, square, triangle and trapezoid-loads.—A. E. BEITLICH

Stirrups in concrete beams located with charts. T. GERMUNDSSON. *Concrete*, May, 1931, V. 38, No. 5, p. 41-42.—A large chart has been constructed, based upon usual method of determining spacing of stirrups and composed of a series of vertical lines for each size of bar commonly used. It is necessary to calculate total shear to be carried by stirrups at two points, at support and at center of span. A line connecting these two points on the chart enables designer to read directly number of stirrups required and their spacing. —N. H. ROY

Short-cuts in structural design. JAMES R. GRIFFITH. *Concrete*, April, 1931, V. 38, No. 4, p. 36-38.—Chart II gives intensity of pressure under footings. Chart resembles a contour map of a hill. It may be used in computing soil pressures under foundation walls of buildings, chimney footings, bridge piers and similar cases. To use the chart, overturning moments must be calculated. These moments are taken about base and parallel to either side of structure. Maximum pressure under footing is a constant, K_r, times the unit load on the base. The value K_r is read from the chart, using the overturning moment, the total load on the base and one dimension of the base.—N. H. ROY

Application of influence lines to the design of rigid frames. W. CHERRE. *Concrete Construction Eng.* (England) April, 1931, V. 26, No. 4, p. 252-64.—Method of constructing influence lines for moments and shears in rigid frames, is based upon assumed variation in moment of inertia expressed by an equation giving moment of inertia at any section in terms of that at center of span, length of span, ratios of inertias at center and at supports, and a coefficient. Expressions are derived for moments at ends of spans in terms of rotations at ends. Equations defining positions of fixed points are determined, from which rotations of girders and columns of frames are obtained. From values of rotations, bending moments due to unit loads for different sections are found and plotted. From these curves influence lines are drawn. Method of constructing influence lines for shear is outlined.—JOSEPH MARIN

Nomogram for calculating the allowable distance between vertical or inclined stirrups of beams and slabs as determined by diagonal tension and shear. JORGE QUIJANO. *Ingenieria* (Mexico), June, 1930, V. 4, No. 6, p. 253-254. A nomographic chart for use in designing or investigating the distances between vertical or inclined stirrups, which solves the relation $T = S\,(v—2.8)b$.—(Author's correction to 5th abstract, A. C. I JOURNAL, Jan. 1931; *Abstracts* V. 2, p. 146).

ROADS AND PAVEMENTS

Where more research is needed in concrete highway work. *Concrete* April, 1931, V. 38, No. 4, pp. 33-34.—Replies to inquiry among engineering officials of state highway departments indicate more information is needed on a number of problems, in approximately following order of importance: (1) Studies of subgrade soils, drainage and frost action, and their relation to concrete pavements. (2) Design of concrete mixtures, with special reference to simplicity of procedure. (3) Factors affecting durability of concrete. (4) Design of pavement slabs and sections, and studies of slab action. (5) Comparative efficiency of improved methods of curing. (6) Traffic surveys. (7) Concrete materials for highway pavements. (8) Use of coarser sizes of aggregates in concrete mixtures. (9) Construction methods. (10) Causes and prevention of cracking. (11) Studies of cement.—C. BACHMANN

Cement joints in concrete roads. C. H. CONNER. *Canadian Engineer*, March 31, 1931, V. 60, No. 13, p. 24.—Inspections show that concrete pavements with properly placed steel reinforcement, divided longitudinally and transversely by joints give far better service than plain concrete without joints. Generally all pavements 18 ft. or wider are divided by longitudinal joints. Some are cut through pavement and joint filled with filler while others may be hidden or partially cut through. Spacing of transverse joints usually varies between 30 and 50 ft. Present tendency is toward use of wide expansion joints

spaced at rather wide intervals with one or two contraction joints between them, such as ¾ in. expansion joint at 80-ft. intervals with one dummy contraction joint at 40 ft. intervals for a 40-ft. spacing. Generally a 1-in expansion interval for each 100 ft. of slab is recommended.—G. M. WILLIAMS

ARCHITECTURAL DESIGN

The new telegraph construction office building in Stuttgart (Germany). *Zement* (Germany), March 12, 1931, V. 20, No. 11, p. 247.—Large structure was built entirely of reinforced concrete. Building, 460 ft. long, is especially distinguished by precision in construction of exterior and interior. Architectural design is discussed.—A. E. BEITLICH

The architecture of reinforced concrete in Holland. J. DUIKER AND G. MEYERS. *Summary Reports First I. C. for C. and R. C.*—In Holland, as in other countries, reinforced concrete architecture has no existence as a characteristic national architecture. The architecture which is characteristic of reinforced concrete derives from the skeletal form of construction adopted; outside walls carry no load but serve only to separate the interior from the exterior. Such a way of building can allow a front wall almost entirely of glass. Style is determined by the principle which underlies construction; thus it may be noted how Classical and Gothic construction gradually acquired greater lightness and delicacy. It is in this way that reinforced concrete may lead to the development of a new style.—LA TECHNIQUE DES TRAVAUX

Decorative concrete. JOHN J. EARLEY. *Concrete Products*, April, 1931. V. 40, No. 4, p. 50-52.—In review of work done by the writer in developing use of color in concrete by means of colored aggregates, he states that recently a doubt has arisen not as to superiority of exposed aggregate method but as to universality of its application. Its use is likely to be restricted, leaving need for another treatment of concrete for more general use. This will perhaps take the form of a surface treatment though one that will be more nearly an integral part of the concrete itself than anything so far developed.—E. S. HANSON

The new reinforced concrete bridge with artificial granite surface over the Escaut at Eyne, Belgium. E. TASHJIAN. *Genie Civil*, (France) April 11, 1931, No. 15, p. 376-377.—Bridge built by State of Ohio in commemoration of the passing of the 37th Division of the American Army in October 1918, replaces structure torn down in 1914 by retreating allied armies. Its graceful lines, decorative sculptures and artificial granite surface are much admired. It was designed by Walker & Weeks, Architects, Cleveland, Ohio and erected by Messrs. De Cavel, Chief Engineer, Heylbroeck and De Nayer, Assistant Engineers of Roads and Bridges, Belgium. Artificial granite forms an integral part of structure, being poured into a space next to form, separated from the interior by a wire mesh, keeping in place special aggregate consisting of 40 per cent quartz, 40 per cent white Carrara marble, 20 per cent black Carrara marble. White cement was used.—M. A. CORBIN

FIELD CONSTRUCTION

BRIDGES

Arch bridges. "Bogenbruecken." C. KERSTEN, 1930, Wilhelm Ernst and Son, Berlin (Germany), second volume of: Reinforced concrete bridges "Bruecken aus Eisenbeton," 5th revised edition. R. M. 16.50. Reviewed in *Zement* (Germany), March 5, 1931, V. 20, No. 10, p. 226.—In a comprehensive treatise on construction of reinforced concrete arch bridges, numerous forms and systems are arranged according to different viewpoints. Examples of loading tests are of special value for consideration of questions of static. Construction and centerings are described besides presentation of static calculations.—A. E. BEITLICH

The use of pre-cast reinforced concrete slabs for bridge floors. RAFAEL CEBALLOS PARON. *Summary Reports First I. C. for C. and R. C.*—This

paper describes the arrangements for handling reinforced concrete slabs, precast in quantities off the site, for eventual use, suitably erected, to form the floor of a double track railway bridge of concrete.—LA TECHNIQUE DES TRAVAUX

Concrete trusses and 47-ft. flat slabs in new Seattle viaduct. CLARK H. ELDRIDGE. *Eng. News Record*, April 16, 1931, V. 106, No. 16, p. 642.—The West Garfield St. bridge recently completed in Seattle at a cost of about $750,000 includes heavy one-way flat slab construction on spans up to a maximum of 47 ft., and reinforced-concrete trusses 60 ft. long. Structure is 3010 ft. long, with a 36-ft. road and two 6-ft. walks. To meet design stress of 1200 lb. per sq. in., a 1:2:3 mix was used which attained an average 28-day strength of 3867 lb. per sq. in. Both trusses and deck were concreted in one operation.—GLENN MURPHY

Study of viaducts of variable span. G. GARAT. *Genie Civil*, (France) Jan. 31, 1931, No. 5, p. 109-114.—About 50 viaducts are under construction at present on the line Tanap—Thakhek, Indochina and consist of reinforced concrete spans resting on masonry supports. Spans vary from 19.7 ft. to 49.2 ft. Ease of construction and esthetic considerations have led to adoption of constant depth for all spans. Careful cost analysis including numerous diagrams representing cost per meter of the viaducts, showed that no appreciable cost increase was produced by adopting a constant depth.—M. A. CORBIN

Construction of a bridge over river Glan in Odernheim for highway between Homburg and Bingen (Germany). SEYWALD. *Zement* (Germany), Feb. 5, 1931, V. 20, No. 6, p. 125-9.—Old structure which had suffered by increased traffic during war time was replaced by reinforced concrete arch bridge. Sound underground was found in a depth of 20 ft. Span of single arch is 131.2 ft., roadway is 19.7 ft. wide and has a 4.1 ft. wide sidewalk on either side. Arch is provided with 3 lead hinges. Foundations were made in open excavations protected by Larsen steel sheet pilings. Centering is of normal design. Of special interest are expansion joints. A 1:4:8 concrete mix was used for abutments, 1:2:3 and 1:3:5:6.5 mixtures for arch and a 1:2:3 mix for roadway slab.—A. E. BEITLICH

Bridge piers in Suisun Bay supply test of concreting methods. C. R. HARDING. *Concrete*, April, 1931, V. 38, No. 4, p. 9-11.—To prevent shattering by earthquake, piers for railroad bridge, across Suisun Bay, at San Francisco, were heavily reinforced with steel rods. Concrete was controlled by W/C ratio method. Rock and sand were weighed, and cement, to which was added 3 per cent diatomaceous silica, was added from sacks. Adjustments were made for free water in aggregate. Concrete was mixed 90 seconds after all materials were in the mixer. Concrete mix, by weight, of 1:2.5:4.4, included 5 sacks of cement per cu. yd. and 6.75 gal. water per sack. Compressive strengths per sq. in. were 2,000 and 3,200 lb. at 7 and 28 da. Eight pedestal piers, located on land were built in wood forms, pier footings resting directly on bedrock. Mix was 1:2.42:4.04 by weight, with 5.46 sacks cement per cu. yd., and 6.25 gals. water per sack. Average compressive strengths were 1,760, 2,630, and 3,350 lb. at 7,14 and 28 da. Wood forms for 14 pedestal piers were built inside cofferdams and concrete placed in dry. Concrete for shafts was 1:2:3 mix by volume, with 6.49 sacks cement per cu. yd. of concrete, and 5.25 gal. water per sack of cement. Strengths were 2,700, 3,500 and 4,500 lb. per sq. in. at 7, 28, and 90 days.—C. BACHMANN

Reinforced concrete bridge with rigid reinforcement. *Genie Civil* (France), Feb. 7, 1931, No. 6, p. 139-141.—To reduce dead weight, bridge near Echelsbach, Bavaria, across the Ammer with a 426.5 ft. span, and rise of 104.3 ft. was designed as two arches of rectangular section, measuring 4.9 ft. in width and varying in depth from 6.56 ft. at crown to 10.5 ft. at skewback. These arches are spaced 19.7 ft. axis to axis and are hollow. Special feature of bridge is its reinforcement, which permitted erection without false work with independent

foundations. Bridge was erected cantilever fashion and was encased in concrete using light forms, this system of rigid reinforcement being known as Melan and Spangenberg system. Its application for a large span presented difficulty of ascertaining variable stresses produced by progressive concreting. Before concreting bridge was subjected to a load of gravel equivalent to total load it was finally to support, this load being removed as concreting progressed. —M. A. CORBIN

The Lorraine bridge over the river Aare in Bern (Switzerland). ROB MAILLARD. *Schweizerische Bauzeitung* (Switzerland), Jan. 3, 10, 17, 31, 1931, V. 97, No. 1, 2, 3 and 5, p. 1-3, 17-20, 23-6, 47-9.—Center arch of large concrete highway bridge has elliptical shape and span of 262.5 ft. Two circular arches with spans of 55.8 ft. support approaches on either side. Large concrete blocks, surfaces of which were treated by Contex method, were used. Abutments rest on sound rock. Roadway is provided with two cantilevered sidewalks, and is supported by 8 horizontal and 44 transverse concrete walls. Center and side arches are separated by expansion joints. Concrete mixing plants were located on either side of river. Centering of middle arch had unusual design. Placing of concrete blocks was started from both sides by cable crane. Data are furnished concerning physical tests of structural materials, laboratory tests, observations of movements in arch and temperature measurements.—A. E. BEITLICH

Repair of the Wallstrasse bridge in Ulm. K. SCHAECHTERLE. *Beton u. Eisen* (Germany), Jan. 5, 1931, V. 30, Heft 1, p. 14-18.—The Wallstrasse bridge (cf. *Bauzeitung* (Germany), 1906, Nos. 1, 7, 11) a three hinged open spandrel arch over the State Railroad built in 1905 has until recently given satisfactory service, with practically no maintenance cost. Clear span is 215 ft. with 187 ft. between the abutment hinges, and the rise 19 ft. The superstructure is 34 ft. wide. Arch concrete (stiff 1:3:5) showed a 57-day strength of 4800 lb. per sq. in. and the deck concrete (soupy 1:4¼) a 28-day strength of 2300 lb. per sq. in. In the last few years damp and wet spots appeared on the underside of the deck, water began to drip at the expansion joints and cracks and spalling became noticeable, particularly along the cantilevered side walk. Investigation revealed that slight changes in the original design would have prevented this deterioration. Where spalling had started, or where underspace of slab was wet, rusting of slab steel was found. In some places steel was exposed. Hair cracks and action of smoke led to much of rusting of reinforcement in portions above tracks. A lead and asphalt membrane used to water proof roadway, seems to have given fairly satisfactory service. Plain asphalt coating used for sidewalks proved inadequate due to cracking and to poor details along railing and curb. Damage was not serious enough to warrant expense of rewaterproofing the entire structure. Faulty joints along railing and curb were repaired and rusted steel was exposed and covered with fresh mortar. A groove was cut in the underside of sidewalk slab to act as a drip. Drains were provided along expansion joints. Paving was treated with a waterproof covering. After slabs were dry the entire soffit of deck slab received a waterproof coating. The following recommendations are made. Drainage should be promoted by covering upper surface of structure with a jointless asphalt coating or something similar. Both bearing surface and surface of structural slab should be given sufficient grade and lateral slope. Sliding plates over expansion joints should be avoided for ordinary spans. Percolated water should not be permitted to cross expansion joints. Waterproofing should not be given sharp bends and should be carried up a short distance at railing and curbs.—A. A. BRIELMAIER

BUILDINGS

Theatre and restaurant Des Ambassadeurs at Paris. L. GELLUSSEAU *Genie Civil*, Jan. 24, 1931, No. 4, p. 77-81.—Structure comprises a large dining room with stage and a theatre with 1000 seats. Work progressed rapidly due

to use of a skeleton of reinforced concrete. The structure is 85 by 207 ft. and is very low—21.5 ft.—to be in keeping with general character of the Champs Elysées. With exception of two steel trusses entire structure is of reinforced concrete. To reduce time of placing, only cement of high strength was used. Entire job was completed in less than three months, a record according to European standards. Live load used in the design was 495 lb. per sq. ft. Tests showed short-time placing of concrete in no way impaired its strength.—M. A. CORBIN

New high buildings in Duesseldorf (Germany). WILHELM PETRY. *Zement* (Germany), Jan. 22, 1931, V. 20, No. 4, p. 79-82.—(1) In the enlargement and reconstruction of tall reinforced concrete office building, basement structure was protected against ground water by insulation of interesting design and will stand a water head of 16 ft. Superstructure is of skeleton type consisting of one inner and one outer row of columns. Span of horizontal connecting beams is 23.8 ft. (2) Municipal bath house has 2 indoor swimming pools, 82 ft. by 36 ft. and 82 ft. by 41 ft. Both rest on separate reinforced concrete foundations to prevent harmful stresses in case building settles.—A. E. BEITLICH

The new structures of the Bavarian Dairy Co. in Nuernberg (Germany). HERMANN MEIER. *Zement* (Germany), March 19, 26, 1931, V. 20, No. 12-13. p. 274-8, 304-6.—Remarkable features of a number of reinforced concrete dairy structures include ceilings with very large spans. Main building is reinforced concrete skeleton structure, 354 ft. long and 79 ft. wide. Distances between reinforced concrete columns are 19.7 to 37.5 ft. Main roof has reinforced concrete ceiling with spans from 78.7 to 121.4 ft. without supporting columns. Building is provided with 3 expansion joints. Reinforced concrete chimney was erected by Heine method with sliding forms. Two water tanks having a total capacity of 42,000 gallons and arranged circumferentially around chimney, are supported by a circle of 8 reinforced concrete columns, 65.6 ft. high, connected by 2 horizontal concrete rings. Foundation consists of 5 ft. reinforced concrete slab, an octagon with outer diameter of 41 ft. High early strength cement was used for chimney construction.—A. E. BEITLICH

DAMS

Construction features of Osage hydro-electric development. *Eng. News Record,* March 26, 1931, V. 106, No. 13, p. 523-528.—Many interesting construction features are involved in Osage hydro-electric project near Bagnall, Mo. Power house forms 511 ft. of total length of dam, which is 2543 ft. Spillways constitute 520 ft. of crest. The maximum height is 148 ft. Concrete was made at central mixing plant, so located that 70,000 cu. yd. was chuted directly into place. Remainder was hauled in hoppers on flat cars over a construction bridge from which it was placed either by chutes or gantry crane. Four 60-cu. ft. mixers were used, giving a maximum 24-hr. output of 5082 cu. yd., with a 2-min. mixing period. The total yardage was 551,000.—GLENN MURPHY

Placing 350,000-cubic yards of concrete in Ariel dam. W. A. SCOTT. *Concrete,* March, 1931, V. 38, No. 3, p. 13-16.—Equipment for recovery of sand, gravel and cobbles from river deposit, washing and screening, bulk cement storage, proportioning and mixing, and conveying by belt was installed in construction of Ariel dam and powerhouse. Aggregate was transported 1000 ft. from river and dumped into bunker. Bulk cement was hauled 12 miles to storage. Water-cement ratio in mixer batch ranged from 0.9 to 1.0, including aggregate water. Concrete batches were discharged from mixers into 2-yd. bottom-dump buckets, carried on flat-cars and pulled alongside any section of dam, where buckets were lifted by crane or derrick. Expansion and contraction joints for all sections were placed at average of about 30 ft. Joints in arch section were 2 ft. wide, allowing arch to be built up in 30 ft.

sections, separated by 2-ft. slots, to be filled with concrete after shrinkage. Spillway contraction joints were grouted through series of pipes after shrinkage. —C. BACHMANN

Ariel dam—example of modern engineering practice. *Eng. News Record*, March 12, 1931, V. 106, No. 11, p. 435.—A site considered so difficult that 26,000-ft. of drill holes were put down to explore it, a foundation excavated 125 ft. through gravel to bed rock on site of ancient waterfall, and careful concrete control are among construction features of Ariel Dam of Inland Power and Light Co., on the Lewis River in Washington, about 40 miles northwest of Portland, Ore. The 313-ft. structure, with 1300-ft. crest, of thin-arch type requires 300,000 cu. yd. of concrete, 95,000 cu. yd. of which are in the one gravity abutment. Sand and gravel are excavated, washed, and screened on the site. Aggregate is graded to two sizes, ¼-1¼ in. and 1¼-3. Mix is 1:3.4:6.6 by weight, with w/c of 0.97, giving average compressive strength of 2,600 lb. per sq. in. at 28 days. Three 2-yd. mixers, with time of mixing 2½ min., enable workmen to average over 1.6 cu. yd. per min. of placed concrete. Concrete is placed in 12 in. layers in 5-ft. lifts in gravity section and in 10 ft. lifts in arch section. Vibration of concrete is accomplished by a steel shoe carrying a small portable gasoline engine with an eccentric flywheel. To reduce heat generated and resultant shrinkage stresses, the arched section of the dam is built in sections 30 ft. long separated by 2-ft. spaces to be filled six months later. Studies with electric thermometers indicate arrangement is most successful. Tests indicate rapid cooling may be obtained by circulating water through pipes cast in the block. It was found that concrete placed at 60° F. will rise to a maximum of 140° F. during curing process.—GLENN MURPHY

MISCELLANEOUS

Concrete and reinforced concrete in the Colony. M. DAVID. *Summary Reports First I. C. for C. and R. C.*—This paper discusses general conditions under which concrete and reinforced concrete are built in the (Belgian) colony—reasons why works in durable material, especially concrete, have to be adopted; conditions to be fulfilled; remarks on colonial materials (cements, sand, gravel, and in particular, laterite concrete); means and methods of execution; labor; and costs.—LA TECHNIQUE DES TRAVAUX

The application of concrete in the Belgian Congo. R. COPPEE. *Summary Reports First I. C. for C. and R. C.*—Special conditions governing the choice of concrete as material for construction in the Belgian Congo are: Climatic effects on works, other destructive agents peculiar to tropical regions, delivery time and costs for other materials, poor quality of other materials.—LA TECHNIQUE DES TRAVAUX

The manufacture of pre-cast reinforced concrete pieces on the Belgian National Railway Co. C. LEMAIRE AND J. SCHOTTE. *Summary Reports First I. C. for C. and R. C.*—Organization of a work yard. Quality and specifications of raw materials. Description of the various operations involved in the manufacture. Descriptions of the articles manufactured and of the shuttering used in quantity production.—LA TECHNIQUE DES TRAVAUX

Experimental study and description of constructional elements in reinforced concrete. LOUIS BAES. *Summary Reports First I. C. for C. and R. C.*—(1) Farco metal as a material for centering and as reinforcement. Farco metal is formed of very thin steel sheets specially formed with projecting sides giving a certain stiffness. These sides are joined by a trellis with a mesh sufficiently small to retain the concrete. (2) Experimental study and description of reinforced concrete tubes made by rolling and intended to resist bending (process Tubarsi). The note describes the process of fabrication by rolling of tubes of concrete heavily reinforced longitudinally.—LA TECHNIQUE DES TRAVAUX

Special reinforced concrete piles. M. E. H. TJADEN. *Summary Reports First I. C. for C. and R. C.*—The "de Waal" system is as follows: hollow cylin-

drical pile is built of reinforced concrete and driven into ground down to a hard stratum; working through hollow an enlarged foot is formed; then the inside is filled with concrete. The piles may either be formed in situ or precast in pieces about 8 ft. long.—LA TECHNIQUE DES TRAVAUX

A casting operation of reinforced concrete piles. J. VILAR. *Summary Reports First I. C. for C. and R. C.*—Bridge required 800 reinforced concrete piles about 32 ft. 10 in. long, and as the space available for casting them was confined to 164 x 66 ft., a procedure had to be devised whereby they might be superimposed. This was effected by placing sheets of thick paper between adjacent piles to prevent bonding with one another, thus taking up the least possible space.—LA TECHNIQUE DES TRAVAUX

New methods of forming piles cast in situ. L. F. DE JESSEN. *Summary Reports First I. C. for C. and R. C.*—Foundation piles cast in situ are perfectly adapted to nature of soil and varied forces which a foundation must resist. Three solutions recently applied are: (1) Drawing of the tube with or without an interior stopper; (2) reinforced inclined piles cast in situ: (3) piles with a base cast in situ surmounted by a pre-cast shaft.—LA TECHNIQUE DES TRAVAUX

Investigation of the effect of frost on concrete with special consideration of the insulating effect of molds. ADALBERT POGANY. *Zement* (Germany), March 12, 1931, V. 20, No. 11, p. 246.—Tests were made with 3 in. concrete cubes. Molds consisted on 3 sides and bottom of 1-in. boards. Fourth side was exposed to temperatures of − 7.6° F. and could be provided with boards of ½ in. to 1¼ in. thickness. Thermometers were located at various places in concrete and temperatures were plotted. Different curves were obtained only during first 30 minutes; afterwards no differences could be noted with boards of different thickness. Exothermic process in concrete such that insulating properties of boards are of minor importance.—A. E. BEITLICH

Hastings promenade widening works. *Engineering* (England), April 3, 1931, V. 131, No. 3403, p. 446.—In rebuilding shore promenade at Hastings a sea wall was built at outer line by driving two rows of watertight sheet steel piling between which, after excavation, a concrete wall of "Sal Ferricite" was placed. This wall has a curved face and is finished off with a larger radius nosing to break force of the waves. Steel rails were used for reinforcement.—G. M. WILLIAMS

Pre-cast caisson impounding wall at Weston-Super-Mare. *Engineering* (England), April 10, 1931, V. 131, No. 3404, p. 477.—To increase bathing facilities at Weston-Super-Mare an artificial lake has been created on the beach to impound flood tide. A heavy wall was required to withstand strong gales together with high tides. Caissons of reinforced concrete 20 ft. long 12 ft. wide and 9 ft. high with the interiors divided into four equal portions by longitudinal and transverse wells were built with rapid hardening Ferrocrete cement in a sheltered cove and floated into position and sunk by filling compartments with sand. A 1:1½:3 concrete mix was used. Before floating caissons into position a base was prepared by excavating pits in shore sand and refilling with mass concrete and boulders; these pits being spaced so that each served to support adjoining ends of two caissons. Space of several feet between caisson ends was filled with mass concrete in which Stanton spun concrete sluice pipes were cast. After placing caissons the height was increased 2 ft. by addition of concrete blocks. A sloped retaining wall, rising at an angle of 30 deg. made up of boulders and faced with a thick layer of boulder concrete was placed on sea side of caissons with toe protected by sheet piling.—G. M. WILLIAMS

New ocean terminal at Halifax, N. S. *Canadian Engineer*, Feb. 10, 1931, V. 60, No. 6, p. 22.—Pier B unit recently constructed in Halifax Harbor consists of 30 reinforced concrete cribs, with depth of water varying from 35 to 45 ft. at low tide. Cribs are 108 ft. long, 52 ft. wide and 53 ft. 6 in. high for outer 18 and the same length but width of 42 ft. and depth of 42 ft. 6 in. for inner 12.

Special construction dock having a water depth of 35 ft. at low tide was built. Cribs were started on pontoons and after a certain height was built were launched and completed while floating. After completion these were towed to position and sunk by letting water into pockets. Cement Fondu, imported from England was used.—G. M. WILLIAMS

Cement calendar 1931. "Zement Kalender 1931." RIEPERT, 1930, Zementverlag, Charlottenburg, (Germany), RM. 3.60. Reviewed in *Bautechnik* (Germany), March 20, 1931, V. 9, No. 13, p. 198.—A few new additions to this book include special concreting methods, new application of concrete pump (Pumpkret-method). Chapters on cement pipes, concrete wells, cement roof tiles and concrete slabs for sidewalks are enlarged.—A. E. BEITLICH

Swimming pool at Chateau Laurier. *Canadian Engineer*, Feb. 29, 1931, V. 60, No. 8, p. 11.—Canadian National Railway has completed a modern swimming pool as part of therapeutic department at Hotel Chateau Laurier at Ottawa. Pool is 25 ft. wide, 60 ft. long and from 3½ to 9 ft. deep, lined with mosaic tile and lighted under water. Reinforced concrete was cast as a unit to avoid weakness at joints.—G. M. WILLIAMS

Physics for construction technique. "Bautechnische Physik." HIMMEL-STROH-MEYER, 1930, B. G. Teubner, Leipzig and Berlin (Germany), sixth edition, R. M. 5.40. Reviewed in *Zement* (Germany), March 5, 1931, V. 20, No. 10, p. 226.—This book treats physics from standpoint of construction practice and shows examples of physical reactions and of physical installations for construction work.—A. E. BEITLICH

Government grain elevator at Prescott. E. SMITH, *Canadian Engineer*, April 7, 1931, V. 60, No. 14, p. 19.—A 5,000,000-bushel terminal grain elevator, erected at Prescott, Ont., by Dominion Government, has length of 1285 ft. and width of 70 ft. made up of 125 circular tanks with an internal diameter of 20½ ft., and 190 interspace tanks. The height is 85 ft. and wall thickness 7 in. After driving piling and cutting them to grade an 18 in. thick reinforced concrete mattress was placed.—G. M. WILLIAMS

Concrete blocks supplant ties in experimental track. *Eng. News Record*, March 26, 1931, V. 106, No. 13, p. 514.—Track construction without ties, but with pairs of reinforced-concrete blocks connected by tiebars, is being tried on a practicable scale in Italy, and is to be applied more extensively. Blocks are 24x44 in. on the base, and 36x16 in. on top, top surface being sloped 1 in 20 to give the rail an inward cant. The thickness is 8 in. on outer side. Rail rests on a metal plate, under which is a ½-in. wood cushion block. Fastenings are provided so gage is adjustable.—GLENN MURPHY

Concrete units hold embankments. *Concrete Products*, March, 1931, V. 40, No. 3, p. 36-37.—Construction of an unusual retaining wall, involving use of approximately 48,000 5x8x12-in. concrete building tile furnished by San Angelo Building Material Co. was completed recently at plant of the West Texas Utilities Co., San Angelo, Texas. This retaining blanket is approximately 50x410 ft. and has a wall area of over 20,000 sq. ft. Panels, measuring about 10x12 ft. each laid on a 30 deg. slope, are tied together with reinforced concrete beams formed of same tile to prevent settlement of areas greater than 120 sq. ft. In this retaining wall, which protects a spray pond located near a small stream, concrete tile was bid on and placed for $1.35 per sq. yd. less than bid for rip-rap.—E. S. HANSON

Precast concrete pipe supports. *Conc. Building Conc. Prod.*, (England), April,1931, V. 6, No. 4, p. 1.—Reinforced concrete pipe trestles, consist of two raking columns, with two or more horizontal bracing members. Longest trestles are molded first, molds being cut short at level of top of one of braces, and a new end piece fixed. The concrete mix is 1:2:4, with rapid hardening cement. Trestles are from 7 ft. 6 in. to 20 ft. overall, and the heavier ones are lifted by shear legs after four or five days. They are slung into position from top and upper brace. Bottom of trestle is buried 1 ft. below ground level in a block of concrete. Another type of trestle consists of three units; footing, pre-

cast column of variable length and standard cap, precast or cast in situ Pyramidal footings are reinforced each way. A 9-in. recess is formed to receive column. A projecting tongue, specially reinforced, forms a key with reinforced concrete cap, which is afterwards grouted on.—JOHN E. ADAMS

Vibration—a new method of working concrete. M. BERENGIER. *Genie Civil* (France), Feb. 21, 1931, No. 8, p. 189-192.—Vibration of forms has given way to vibration of concrete mass itself, a process, which in France is designated as "pervibration." Apparatus generally consists of a shell, within which is enclosed vibrator proper, made of special steel, and operated with compressed air. This vibrator is immersed in the concrete, which acquires the properties of a liquid. When the vibrator is removed, no trace is found of its former location. In general, working of 1.3 cu. yd. may be effected with expenditure of 2 hp. hr. as recorded by compressor. A floating vibrator designed and used successfully on construction of concrete columns, is placed in the form and concrete poured. It rises with each successive pouring. Forms should be watertight. Advantage of vibrating process is elimination of uncertainties inherent in working concrete by hand. Tests made at the Laboratoire des Ponts et Chaussées demonstrate that high strengths may be obtained through vibration with poor mixes, strength, permeability and compactness tests yielding satisfactory results. Great possibilities for ornamental effects are afforded by vibrated concrete, in which the mortar coating of aggregate is very thin, and a compact mosaic effect is produced. Additional expenditures in using a vibrator are: purchase or renting of a vibrator; increased volume of aggregate, corresponding to increased compactness of concrete; watertight forms. Economy of this method results in: reduction of quantity of cement used through higher strengths obtained, which allow reduction of sections; elimination of all hand labor in working concrete; elimination of all finishing work due to very smooth surface.—M. A. CORBIN

Passenger quay "Stazione Marittima" in Triest (Italy). L. GSCHWEND. *Schweizerische Bauzeitung* (Switzerland), Jan. 24, 1931, V. 97, No. 4, p. 35-8.—New quay was connected with old structure by means of hinges to allow room for settling of old wall. Difficulties were encountered in driving reinforced concrete piling which supports 17 reinforced concrete piers of new structure. Piles were 17 in. in diameter and up to 72.2 ft. long. High grade steel tubing, 55.8 ft. long and 19.7 in. in diameter, with a smaller inner steel tubing (end of which was provided with pointed chrome-nickel steel head) were driven through 16 ft. layer of loose rocks. After reaching sound rock inner tubing was pulled and reinforced concrete pile made of high early strength cement was driven. Reinforcements consisted of 8 longitudinal rods and ¼ in. spiral windings. Molds were assembled on shore and concrete of piers was placed under water. Pozzuolana was added to mixture.—A. E. BEITLICH

Continuous conveying as an advancement in construction methods. E. RATHSMANN. *Beton u. Eisen* (Germany), March 20, Apr. 5, 1931, V. 30 Heft 6, 7, p. 117-121, 134-137.—A detailed review gives names of makers of typical machines and some figures on performances of continuous conveying methods for earth, aggregate, concrete etc. Belts and steel bands, in trough form, are suited for moving aggregates and concrete along a 16 to 20 deg. slope with a speed of 4 to 6.5 ft. per second. Troughs and pipes are employed in forwarding concrete, and vibrating troughs for moving dry materials. Conveyors for any slope include bucket chain excavators pneumatic conveyors and pumps. Fuller-Kinyon and Torkret machines are pneumatic conveyors. The former used chiefly for moving cement, depends on intimate mixing of material with air stream and latter is used for moving by means of air pressure, dry mixed concrete materials. The use of compressed air to convey fine concrete, mortar and grout, in a wet state, for cement gun work is widespread. Torkret system of pneumatic transportation of concrete calls for a dry mix, which is dropped into a pressure chamber and forwarded by compressed air through pipes (4 to 6 in. diam.) to discharge chamber where water is added and high velocity of dry

mix is vitiated by impact. Pumps for forwarding materials without the use of water as a vehicle present the latest and simplest method for granular and powdery materials with a small water content. Concrete with aggregate up to 1 in. can be pumped 330 ft. horizontally and 135 ft. vertically. This method almost revolutionizes concrete construction practice and often eliminates lifts, towers and belts.—A. A. BRIELMAIER

Details of movable forms and their operation. RICHARD T. MCKAY. *Concrete*, April, 1931, V. 38, No. 4, p. 12-14.—Forms for 8 concrete tanks with inside diameter of 29 ft. 9 in., walls 7 in. thick and 100 ft. high, have top diameter slightly larger and bottom diameter smaller. Mean thickness of wall 2 ft. from top is 7 in. Top of upper ring of segments is kept down 5⅝ in. so 2x6 in. joists space 16 in. center to center for supporting 1 in. decking can rest directly on them. Three rings of 2 by 8 in. segments, both top and bottom, are spiked together and laid so that, in their lengths, they lap each other. Staves are nailed to segments. I-beams over each row of tanks are set in moving forms and carried up with them to support roof slab over completed tank walls and also to support 2 by 6 in. joists that carry 1 in. decking placed over entire inside area of tanks. Deck is used for storage of bars placed as work proceeds, and is concreting deck. Exact placing is not necessary of jack rods. To pull between 60 and 70 sq. ft. of forms to each jack, spacing of 8 ft. is suggested. With forms 4 ft. deep on each side of wall, this spacing would give 64 sq. ft. of contact area to be pulled by each jack.—C. BACHMANN

Concrete mixture design controlled by Chicago & North Western. O. F. DALSTROM. *Concrete*, April, 1931, V. 38, No. 4, p. 21-24.—Instructions for designing concrete mixtures issued for information of its contractors and for use of its engineering and inspection forces by Chicago and North Western Railway are as follows: Form BD-1 is to be used whenever concrete is made. One copy completely filled out is to be sent to engineer of bridges as soon as concrete work is started, or before. The source of the aggregates should be determined and recorded on form. Soundness and colorimetric tests are recommended when value of aggregates is doubtful. Aggregates must satisfy specification requirements as to structure and cleanness. Concrete is noted on plans as Class A, B, or C. For Class A, strength at 28 days should be 3,000 lbs. per sq. in., requiring a maximum of 5½ gals. of water per bag of cement; Class B, 2500 lbs., with 6¼ gals. of water; Class C, 2000 lbs., with 7 gals. of water. Representative sample of aggregate is to be taken about a foot in from surface and half-way up stock-pile. Grading is next determined and entered, followed by field mix by volume and net quantity of mixing water. Yield is determined without calculations by reading scale. After mix design is complete, check should be made by trial batch, workability of which is measured by slump method. After concrete operations are under way, frequent determination of the moisture content of aggregates should be made and adjustment made at the mixer.—C. BACHMANN

Chicago and North Western instructs inspectors of concrete. O. F. DALSTROM. *Concrete*, March, 1931, V. 38, No. 3, p. 30-32.—At inauguration of controlling quality of concrete in field, railroad required own engineering and inspection forces to attend Portland Cement Association course of instruction on subject. Course has been repeated every spring since. Written instructions to inspectors form next step. Included are emphasis on w/c ratio method, list of specifications, directions, references and blank forms inspector should carry, list of equipment contractors and railway construction crews should have on job. Specific duties of inspectors are outlined in ten paragraphs.—C. BACHMANN

New quay walls in Hamburg (Germany), discussed from constructive and economic view point. K. BARITSCH. *Report 33rd main meeting German Concrete Association*, March 17, 1930, p. 430-67.—A great number of new harbor structures are described in all details, with drawings, graphs, and static calculations, and costs of similar structures are compared. Following rein-

forced concrete structures are included: (1) Quay wall for Deutsche Werft, A. G., consists of 2 sections which are 820 and 666 ft. long. Latter part supports 80-ton traveling crane which reaches 165 ft. (2) Similar structure was built for wharf of Blohm and Voss. (3) Quay for Rhenania-Ossag Oil Co., shows interesting design (cf. *Zement* (Germany), Jan. 8, 1931, V. 20, No. 2, p. 39-40). (4) Reinforced concrete quay wall on east side of harbor in Cuxhaven (Germany). Detailed cost calculations are given.—A. E. BEITLICH

Dustproof concrete floors. *Conc. Bldg. Conc. Prod.* (England), March 1931, V. 6, No. 3, p. 42.—Concrete floors when properly prepared and laid should stand heaviest traffic without serious trouble from dusting or disintegration. Main causes of a dusting surface are: foreign matter in the aggregates; too much cement or fine aggregate; too wet or too dry mix; excessive trowelling; exposure of surface to action of frost; too rapid drying of surface; practice of sprinkling surface with neat cement. The finished surface should always be kept damp for 7 days at least, and increased resistance to wear may be obtained by treating surface with solution of sodium silicate. A 30.5 per cent solution of neutral sodium silicate diluted with about 4 times its volume of water, well brushed over floor and application repeated after 24 hr. has given good results. A vegetable oil such as tung oil may be applied neat, or diluted with turpentine or white spirit and freely applied, excess being wiped off after 2 hr. A second application is sometimes necessary if floor is very porous.—JOHN E. ADAMS

The eight-mile Cascade tunnel of the Great Northern Railway. A symposium. D. J. KERR, FREDERICK MEARS AND J. C. BAXTER. *Proc. Am. Soc. C. E.*, Feb., 1931, V. 57, No. 2, p. 184-268.—Symposium constitutes final professional record of this project and consists of Part 1, an historical outline; Part 2, a description of the surveying methods; and Part 3, detailing methods of construction. This 7.79 mile tunnel (longest railroad tunnel in the Western Hemisphere and fifth longest in the world) replaces a 2.7 mile tunnel completed in December, 1900, and which lowered the Cascade crossing from 4,059 to 3,383 ft. elevation and replaced temporary 4 per cent switchback grades over pass to 2.2 per cent. Tunnel is single track on a 1.565 per cent grade down to the west, concrete lined throughout and was completed in 3 years. The excavated section varied from 18 ft. wide by 25 ft. high to 22 ft. wide by 27 ft. 6 in. high. The tunnel is 16 ft. by 22 ft. 10 in. inside the concrete lining throughout. Excavation proceeded through a pioneer bore supplemented by a 622-ft. shaft in Mill Valley. This shaft cut the tunnel into lengths of 2.41 and 5.38 miles. Center heading followed by top heading and bench excavation was used. None of granitic tunnel muck was suitable for use in concrete lining and entire concreting operation was carried on via east and west portals. On account of conduits side walls were poured in two lifts. Concrete was mixed near the points of deposition. Sand and gravel bunkers equipped with batching devices were constructed near portals. Proportions were nominally 1:2:4, varied to meet variations in the aggregate. Diatomaceons earth was used. A special Blaw-Knox traveling steel form permitted the lining of 37.5 ft. of tunnel at each move. Travelers for form also carried a 14-cu. ft. concrete mixer and air placer and various chutes and elevators. The arch ring was placed pneumatically (cf. H. J. King in Appendix B of paper, p. 261-268). There were 8 of these form placers, 3 of which were operated from west portal and 5 from the east portal. As work progressed removal of forms was shortened from 48 hr. to as low as 8 hr. after final placement, without sign of injury to concrete. The highest rock temperature encountered was 75 deg. (115 deg. had been estimated) and concrete reached 93 deg. about 2 days after placement, cooling gradually to rock temperature after about 2 months. Total yardage of concrete lining was about 275,000.—H. J. GILKEY

Vibrated concrete coating protects underground pipe lines. *Concrete*, March, 1931, V. 38, No. 3, p. 23-24.—Water-cement ratio of 4¾ gal. to sack of cement was disclosed as proper mixture for vibrated concrete for coating underground pipe in studies in Portland Cement Association laboratory. Mixture of 1 part portland cement, 1½ parts well graded sand (0 to ¼ in.) and 3 parts of gravel (¼ to ⅜ in.) was made with 4¾ gal. of water per sack of cement. Mixture appeared dry and unworkable, but was readily placed in forms and around pipe with the use of electrically operated vibrator. Mixture was placed on 10 ft. section of 8⅝-in. O. D. pipe, making concrete covering 1¾ in. thick. Two piece form was made of No. 14 gauge galvanized sheet metal. American Steel and Wire Co., No. 12 welded wire fabric reinforcement, 2 by 6 in. was placed around pipe and held half way between pipe and form. Vibrator was fitted to top of form and operated as concrete was inserted. No honeycombing or segregation of materials resulted. Forms were removed in 24 hr. and concrete cured under damp burlap for 14 days.—C. BACHMANN

Public baths, Westminster. *Ferrocrete Snowcrete Bul.* (England), March, 1931, No. 22, p. 5.—Two swimming baths and over 100 slipper baths, offices, laundry, etc., are included in new reinforced concrete structure at Westminster. Floor of larger bath, which is 100 ft. by 35 ft. and 10 ft. deep at one end, is supported on longitudinal ferro concrete beams, resting on sleeper walls, carried down to firm foundations, and at 16 ft. centres. Additional support is given by columns. Side walls are finished by platform or footway, and floor, which is first covered with asphalt, and walls are lined with Sicilian marble. Staging for spectators is in ferroconcrete and the dressing boxes at gallery level can be folded back to form a dado, and give extra floor space. Smaller bath, which is 70 ft. by 30 ft. is similar except that it is lined with tiles and nosing and scum trough are white glazed fireclay. Roof is semi-circular barrel arch, carried by eight arch ribs springing from foundation slabs below basement level. Clear span is 68 ft. Tubular steel scaffolding was employed to support the timber centering for rib and concrete was mixed at street level and raised in skips by hoist crane at crown of arch. Mix for structural members was 11 cwt. Ferrocrete, 13½ cu. ft. sand and 27 cu. ft. ¾-in. Thames ballast. The mix for walls had only 6 cwt. cement.—JOHN E. ADAMS

Dome built of glass tiles. CRAEMER. *Beton u. Eisen* (Germany), Feb. 20, 1931, V. 30, Heft 4, p. 72.—In the construction of the Indo China Pavilion of French Colonial Exposition several transparent roofs were used. One of domes was built of square glass tiles 15 in. on edge by 3¼ in. thick. Tiles are separated by narrow reinforced concrete ribs, but are so shaped that the dome presents an all glass undersurface and concrete ribs are not noticeable. The dome has the form of a paraboloid of revolution with a diameter of 39.8 ft. and a rise of 4.1 ft. Necessary variation in width of ribs was too small to be evident. Horizontal thrust of dome was taken by a reinforced concrete ring, supporting members being subjected only to the vertical reaction of the dome. Forms consisted of frames with parabolic upper chords spaced at 15 in. Glass tiles were first placed on these open forms and reinforcement and concrete were then placed in spaces between tiles. Parabolic frames were used several times. Several slabs without curvature, were built with same type of glass tiles. These slabs spanned openings as large as 14 ft. 9 in. by 14 ft. 9 in. with a live load of 102 lb. per sq. ft.—A. A. BRIELMAIER

Precast concrete in sea defense work. *Conc. Bldg. Conc. Prod.* (England), Feb., 1931, V. 6, No. 2, p. 21.—Precast concrete units are being used in construction of new sea defense wall and promenade at Bridlington. A new 40-ft. promenade is carried between mass concrete sea wall 1500 ft. long and 16 ft. high, faced with precast concrete units, and existing coast. Reinforced concrete shelters are formed on the inner side of new promenade, with 8 or 9-in. reinforced concrete roof slab carried on 12 by 9-in. beams at 12 ft. 6 in. centres. Beams are supported on back wall and precast columns on front. Columns

are 11 by 11 in. for the lower third of their height and taper to 9 by 9 in. at top. Bases are 15 by 15 in. high, and ornamentally reduced to section of base of column. Similarly ornamented caps are cast on columns. Pine molds were made on the site by the contractors and handled by loco. crane. Reinforcement projects well out of the cap for bonding into beams. Wall facing blocks are composed of 1:2:4 mix, aggregate being obtained from the beach. The seaward faces have a 9 in. facing of concrete made with crushed granite chippings. Blocks ranged from 6 ft. 6 in. by 2 ft. 6 in. by 1 ft. to 3 ft. 6 in. by 2 ft. 6 in. by 1 ft. The upper edges are beveled on the face, each course being stepped back 8 in. at the lower joints to 4½ in. at the top. Triangular recesses are provided in the sides for keying purposes. The promenade paving slabs are 3 ft. by 3 ft. 3½ in. by 4 in. thick, and are made alongside the site on timber molds capable of taking two slabs. The bottom 3 in. of slab is mixed in proportion of 6 parts beach gravel to 1 part portland cement. The 1-in. facing is made with 4 parts crushed granite and black sand to 1 part cement, to eliminate glare. Four recesses are cast on the lower edges of the slab to simplify lifting and transport, and sheets of mesh reinforcement are inserted to prevent cracks.—JOHN E. ADAMS

Screw piles and cylinders. *Magazine Tecnico* (Argentina), Sept.-Dec., 1930.—The screw pile and cylinder are not new but until recently they were impracticable because of complicated equipment required. Usual forms are (1) solid steel piles about one foot in diameter united in lengths of 15 ft. and used for docks, (2) screw cylinder made in diameters up to 4 ft. and lengths of 10 ft. Material is removed as cylinder is lowered and then cylinder is refilled with concrete. (3) Concrete pile with a screw shoe of steel, screw being driven by a steel shaft running through center of concrete. Exterior of the concrete shell is protected by light steel plates. This type is filled with concrete after the drive shaft is removed. Screw piles have screw with diameter about twice that of pile which gives them a greater bearing area. They can be put down and tested and then unscrewed if location is found unsatisfactory. The Braitwaite Co., Ltd., London, have adapted electric capstan to placing of screw piles and cylinders so that now they can be placed to depths of a 100 ft. with rapidity and economy. Electric capstan consists of a framework of steel on which electric motor and reduction gears are mounted. Cylinders are made of steel or cast iron and where diameter is large enough, internal unions are used. The section of the screw or helix is calculated considering screw as a curved cantilever under uniform load using the formula $f = \frac{3\,W\,(R+r)\,(R-r)^2}{\pi\,r\,t^2\,R^2}\left(1-\frac{(R+2r)}{(3R+r)}\right)$ where f = stress at point where helix joins the cylinder. W = load on cylinder. R = exterior radius of helix. t = thickness of the helix at point where it joins the cylinder. The pitch of the helix depends on (a) the material on which the helix is to work, (b) the rate of penetration necessary, (c) the power available in the capstan. The best efficiency is obtained at a velocity of between ½ and 1 revolution per minute of the screw. The power required for the capstans is between 5 h. p. for the small piles and 30 h. p. for the cylinders 10 ft. in diameter. Cost is much lower than for foundations or caissons placed by other methods.—C. G. CLAIR AND M. N. CLAIR

ROADS AND PAVEMENTS

Field determination of cement content of paving concrete. H. ALLEN. *Eng. News-Record*, March 26, 1931, V. 106, No. 13, p. 513.—For determining cement content of mixes proportioned by weight, field equipment consisting of a cast-aluminum measure with a capacity of ½-cu. ft., platform scales, a rod, and a trowel has proven satisfactory. When a standard method of tamping and weighing sample is followed, actual amount of cement in a given sample can be determined quite accurately.—GLENN MURPHY

Concrete roads in Belluno (Italy). *L'Industrie Italiana del Cemento* (Italy), 1930, No. 10; reviewed in *Ostr. Bauzeitung* (Austria), Feb. 14, 1931, V. 7, No. 7, p. 84-5.—Extreme care and construction control is absolutely necessary for good results. Eight sections of highway were built with concrete of varying composition. Road foundation consisted partly of old underground, partly of 6 in. concrete layer. Wire netting was imbedded in concrete. Mixtures contained 440 to 770 lb. cement per 35.31 cu. ft. Reinforcements were prepared by patented special method. Street will be subject to inspections from time to time.—A. E. BEITLICH

Bituminous surfaced concrete sidewalks. A. W. HADDOW. *Canadian Engineer*, March 31, 1931, V. 60, No. 13, p. 19.—City of Edmonton, Alberta, has developed a bituminous surfaced concrete walk consisting of a 4-in. base of 2500-lb. concrete topped with a 1-in. sheet asphalt mixture. Concrete is placed in the usual manner after grading and placing forms with side and transverse retaining shoulders built up to finished surface. Asphalt surface is rolled in place between shoulders several weeks later. Cost is 30c per sq. ft., including all charges.—G. M. WILLIAMS

WATERWORKS

Filtration plant at Brantford, Ont. F. P. ADAMS, *Canadian Engineer*, Feb. 17, 1931, V. 60, No. 7, p. 15.—Brantford, Ont., has completed construction of new pumping and filtration plant, the latter consisting of six 100,000 gallon gravity type rapid sand filters together with mixing chamber, sedimentation basins and filtered water storage reservoir. To insure watertightness a concrete mix of 1:1½:3 was used. The roof of pumphouse and filter building was made of Haydite concrete.—G. M. WILLIAMS

Filters and pumping station connected by concrete conduit. WM. C. MABEE. *Eng. News Record*, April 23, 1931, V. 106, No. 17, pp. 690-692.—Following completion of second large conduit connecting White River filters of Indianapolis Water Co. to Riverside pumping station, careful leakage tests indicated an extremely tight line. Results were more interesting in that conduit passes under Fall Creek and was laid in water-bearing sand and gravel, dewatered with well points. Line is of precast reinforced concrete, consisting of 4400 ft. of 60-in., and 700 ft. of 54-in. copper-bell pipe, in 12½-ft. lengths, 6 in. thick. Pipe was cast in steel forms, with flanged sheet-copper cylinder in pipe bell to provide for expansion and to take up inequalities of grade. The circumferential reinforcement was designed for a head of 25 ft., and longitudinal reinforcement comprised 0.22 per cent of shell area. The concrete was 1:1½:2½, and pipes were moist cured.—GLENN MURPHY

Water purification plant at Ottawa, Ont. A. D. STALKER, *Canadian Engineer*, Feb. 10, 1931, V. 60, No. 6, p. 15.—Work was started in 1929 on a water purification plant having an initial capacity of 35 million gallons daily. Plant, covering an area of 384 by 342 ft. consists of mixing tanks, settling basins and filters together with a filtered water reservoir of concrete. Mix having a slump of 3 to 4 in. with 4.9 to 5.1 gal. of mixing water per bag of cement resulted in strength of 3000 lb. per sq. in. at 28 days. Concrete walls were cured by sprinkling from a ½ in. pipe, perforated at 1 ft. intervals, placed above wall. Flat surfaces were cured by covering with sawdust kept moist by sprinkling. All concrete was kept wet for 14 days.—G. M. WILLIAMS

The use of separated sizes of coarse aggregate in the proportioning of concrete for highway construction. R. W. CRUM. *Nat. Sand Gravel Bull.*, Feb., 1931, V. 12, No. 2, p. 48-52.—Use of coarse aggregate separated into two or more sizes in construction of concrete pavements has been found to be feasible. It does not unduly complicate operations and added cost is small.

Two things can be accomplished by shipping coarse aggregate in two or more sizes and combining them at batching plant. (1) A better grading, having lower void percentage, may be secured than would be possible by taking run of pit. (2) Evil of segregation of sizes in stock piles and cars can be minimized, thus assuring delivery of more uniformly graded aggregate to individual batches. Whether or not this will result in more uniform concrete depends upon importance of coarse aggregate grading in particular concrete mixture being used. From a study of costs of materials and handling, effect of batch size upon cost, workability, durability, and strength and uniformity, it appears that separated sizes of coarse aggregate can be used with uniformity in results if coarse aggregates are furnished in several sizes: and that mixtures with an excess of mortar can be used to produce uniform results without dependence upon control of aggregate grading. An advantage of use of mixtures containing higher percentages of mortar is ease with which workability can be maintained without extra precautions. The controlling factor in choice of type of mixture under specific conditions is largely that of economy in composition of concrete.—P. McKIM

Silicate of soda street foundations. LUIGI BASCHIERI. *Le Strade*, Dec., 1930, V. 12, No. 12, p. 429-440.—Good results have been obtained, in comparison with macadam, with street foundations constructed with calcareous materials and silicate of soda in accordance with the rules given by Guelle of France based on his experiments in 1922. The mix consists of about 1 cu. yd. of graded calcareous stone up to 2 in. combined with ⅓ cu. yd. of calcareous sand or dust resulting from crushing stone and approximately 10 gal. of 35° Beaume sodium silicate. At present experiments are being made to investigate the effect of the variation in proportions on the characteristics of this sodium silicate concrete. A calcareous rock and a quartz rock were used in mixtures with sodium silicate solutions of various densities and compression specimens made from these mixtures were tested at several ages up to 60 days. Limestone aggregate was much superior to the quartz and mixtures with aggregate graded below ⅜ in. were better than those with excess of larger, or smaller aggregate.—C. G. CLAIR AND M. N. CLAIR

SHOP MANUFACTURE

Concrete garden frame. F. BURREN. *Conc. Build. Conc. Prod.* (England), April 1931, V. 6, No. 4, p. 76.—A design for a reinforced concrete garden frame is illustrated, and its advantages outlined. Vibration of concrete into position is recommended, and also a mix of 1:1½:3 with ⅜-in. crushed granite —JOHN E. ADAMS

Precast concrete factory at Liverpool. *Conc. Building Conc. Prod.* (England), April, 1931, V. 6, No. 4, p. 71.—Main features of products, and a description of the nature of recent contracts carried out by a well known firm of precast concrete manufacturers, is given, and illustrated.—JOHN E. ADAMS

"Eternit-Durasbest" and its application in the building industry. H. GROSSMAN. *Zement* (Germany), March 5, 1931, V. 20, No. 10, p. 221-4.—A new type of asbestos cement is used in manufacture of slabs and pipes. Eternit-Durasbest is made of a mixture of 1 part of asbestos and 6 to 7 parts of portland cement. Slabs are made 4 by 8 ft. Excess water is removed under hydraulic press. Pipes can be manufactured in various sizes and thickness of walls is made according to desired pressures.—A. E. BEITLICH

The modern way of manufacture of asbestos-cement pipes. E. LECHNER. *Zement* (Germany), March 12, 1931, V. 20, No. 11, p. 247-50.—A

comprehensive review of publications and patent literature on manufacture of asbestos-cement pipes. Detailed description of methods and installations are given and advantages and disadvantages are described. Methods are also judged from economic viewpoint. Special consideration is given to asbestos-cement pressure pipes, manufacturing methods and their application. Spinning of asbestos pipes resulted in very porous product not suitable for high pressures. Great differences in specific gravities of cement and asbestos cause considerable separation of constituents during spinning process.—A. E. BEITLICH

Profitable manufacture of concrete building units. FRED A. SAGER. *Concrete*, April, 1931, V. 38, No. 4, p. 17-20.—Several methods of handling raw materials are given to illustrate analysis of cost of this part of plant operation. Three methods include placing raw materials in storage by hand, by elevator with bins on ground, and with full elevated bins. In case taken as example, handling operations from car to mixer are (A) shoveling from car to pile, and (B), shoveling and wheeling in wheelbarrows or wheel cart from storage to mixer. Labor rate of 75c per hour, gives cost of 12.5 cents per 1,000 lb. for putting cinders into storage piles. For handling sand or stone as aggregate, suitable labor performance, applicable to those materials, should be used. For wheeling from storage pile to mixer, with 2¼ cu. ft. wheelbarrows, an average run of 50 ft. is taken. Time for filling one wheelbarrow is 40 sec., wheeling, dumping and returning 60 sec., or at a rate of 36 trips per hour, which moves 81 cu. ft., or 4,500 lb. per hour, at a cost of 16.66 cents per 1,000 lbs. Proper runways are effective in reducing cost of operations.—C. BACHMANN

Modern manufacture and use of concrete products and artificial stone. VON MENG. *Beton u. Eisen* (Germany), Oct. 20, 1930, V. 29, Heft 20, p. 357-362.—Modern concrete products have attained their present importance because of the simplicity of manufacture and freedom possible in selection of shape, size and adaptability. Methods of mix design employed in heavy concrete construction cannot be applied to concrete products without some changes. Very thorough study of materials and proportions is essential before production is begun. Fundamental theory, such as that concerning the effect of quantity of water, is same as for mass concrete. In addition to the usual sand gravel and stone, and the natural light weight stones, pumice, lava and tuff there are artificial aggregates including slag, cinders, artificial pumice, porcelain grits, cork, asbestos, treated sawdust, wood wool and others. Selection of aggregate is governed by properties desired in the product; flexibility, compressive, tensile or bending strength, fire resistiveness, impermeability, insulation against heat, sound and electricity, etc. In many cases these properties may be further increased by addition of substances having a chemical or physical effect, as for instance in manufacture of porous concrete. Type of cement and method of concreting have a bearing on resulting properties of the product. Concrete may be poured, vibrated, compressed, squirted or centrifugally cast. Outstanding development is centrifugally-cast pipe, (in Germany mainly Vianini, Dywidag and Hume pipes). These have been replacing to a large extent the welded and riveted iron pipes and wooden pipes. A recent addition is "asbestos cement pipe" (Asbestzenrentrohr) with 2 to 4 in. inside diameter, capable of withstanding 220 lb. per sq. in. pressure and a worthy competitor of iron, steel and cast iron pipes. It is cheaper than metal pipes, light in weight, has a high elasticity and is tough, is a non-conductor of electricity and is not affected by salts or acids within certain limits. Use of concrete for posts, trolley poles, street light poles, etc., has opened up a large field, especially for the centrifugally-cast pole. Concrete paving tiles are cast under 5150 lb. per sq. in. pressure, in pieces 14 by 14 by 3 in. and placed on a subpavement of 1:12 concrete 1¼ to 2 in. thick. Joints were filled with cement grout. Concrete blocks and artificial stone are well adapted to remodeling. —A. A. BRIELMAIER

New Oklahoma pipe plant. DUDLEY W. MOORE. *Concrete Products*, March, 1931, V. 40, No. 3, p. 22-24.—Plant of Oklahoma Cement Pipe Co., Tulsa, Okla. has a daily capacity of 60 to 70 tons of manufactured products of which storm sewer pipe is principal product. Sizes range from 12-in. to 60-in. diameter, made on a machine of revolving platform type. Octagon steel storage bin with five compartments for the storage of stone, sand and cement has capacity of 800 tons. At the top of bin is a turntable distributing device controlled by a wheel and bevel gears from the batching floor beneath the bin so that separate sizes of material are delivered to the various compartments. Discharge is by gravity through a gate into a weighing batcher. Company also manufactures transit mixed concrete.—E. S. HANSON

Betonwerkstein (cast stone). FRIESECKE. *Betonwerk* (Germany), Feb. 28, 1931, No. 9, V. 19, p. 113.—Subject is divided into eight parts: (1) Development of manufacture, selection and use of various aggregates, methods of fabrication and evolution of present designation; (2) cast stone is defended, it is not an imitation; (3) it is a suitable building material, it is strong, withstands weather and is beautiful; (4) present day knowledge of portland cement and concrete mixtures coupled with skill of fabricators is guarantee of good quality; (5) long list of meritorious installations from year 1869 to the present are listed in details; (6) law against willful disparagment of another's product is quoted; (7) observations of experiences of American cast stone manufacturers cited; (8) economy in use of cast stone. Artisans in technique of fabrication are being trained. No pains are being spared in overcoming prejudices and placing cast stone in high place it deserves.—H. FRAUENFELDER

Institute Objects, Organization and Committees

The American Concrete Institute had its beginning in 1905 with organization (incorporated District of Columbia 1906) as the National Association of Cement Users. In 1913 its charter was amended with change of name. With a membership of about 2500 it maintains a continuous program in studying the properties of concrete and reinforced concrete and their constituent materials; considerations of concrete design, manipulation, application, service. Its aims are to increase the knowledge of concrete and to extend the use of that knowledge. It maintains no laboratory, employs no field force. The product of its work is in papers, committee reports and in discussions of them—correlating the experience of many agencies, public and private.

The Institute holds an annual convention as a forum for the presentation and discussion of outstanding developments in the theory and practice of its field, publishes the Journal of the American Concrete Institute monthly, except July and August. The Journal is in three sections: *News Letter*, for the news of the society and informal contributions tending to stimulate its technical program; *Proceedings* for technical papers, reports, discussions; *Abstracts*, consisting of digests of the current periodical literature of cement and concrete.

Proceedings have been published each year beginning 1905; in 1913, 1914, 1915 (Vols. 9, 10 and 11) these were issued periodically in Journal form. A return to the annual volume was made in 1916 with Vol. 12.* Completing Volume 25 in June 1929, Journal publication was again undertaken, No. 1 of Vol. 26 being issued in November, 1929.

The work of the organization is governed by the Board of Direction with 15 members (see By-Laws) and administered by the Secretary, appointed by the Board.

The Board divides the labors of formulating details of the creative program among three major committees: Advisory, originating technical committee assignments; Program, develop-

ing the annual convention; Publications, in general charge of the JOURNAL, which is edited by the Secretary. These committees report to the Board for approval of their undertakings.

In all of this the Institute constitutes a clearing house for the information of and for its chosen field. It is dependent on many public and private agencies and the work of individuals whose studies produce the data for which the Institute offers channels of dissemination and a forum for critical consideration and discussion.

Board of Direction and Executive Committee

The Board of Direction meets at the time of the annual convention; again in the spring (usually early May) and in the Fall (usually the first week of October). Between meetings its authority is vested in the executive committee consisting of the President, Secretary and three other Board members, named by the Board:

D. A. ABRAMS
E. D. BOYER
S. C. HOLLISTER
M. M. UPSON
HARVEY WHIPPLE

*Vol. 11, 1915 is incomplete, numbers 9 to 12 of that year never having been issued. Several numbers of the *Journal* for 1913, 1914 and 1915 are out or print as are also a few of the early volumes of *Proceedings*. Of the *Journals*, Nov. and Dec. 1913; Jan., Feb., Mar. 1914; and Jan., Feb., Mar., Apr., May, June, July and August 1915 are available and are for sale at 50 cents each. A limited supply of annual volumes, 2, 6, 12, 13, 14, 16, 17, 18, 19, 20, 21, 22, so far as available are for sale to non-members at $8.00 each; Vol. 23, 24 and 25 at $10.00 each. The member price for available volumes to and including Vol. 25, 1929, is $5.00 each.

The new JOURNAL is sent to all members (paid for by an allotted portion of the annual dues). Members and JOURNAL subscribers desiring a complete bound copy of Volume 27, containing the *Proceedings* and *Abstracts* sections from the monthly JOURNAL (September 1930 to June 1931), in *addition* to the JOURNAL periodically, may buy it at $6.00. To non-members the price is $12.50.

Orders received from members or subscribers before September 1, 1931 for Volume 28 (September 1931-June 1932) will be filled at a special price—(not to exceed $3.50)—not more than two to each member. The Institute quotes this special price on orders received before the first JOURNAL issue of the volume, because it then knows the actual number of orders to be filled and can provide enough extra copies of each month's JOURNAL to make up the required number for binding. **After September 1, the price will be $6.00 to members,** because such orders must be filled from a limited reserve stock.

Advisory Committee

The Advisory Committee has 13 members: a Chairman, Secretary, the chairman of each of the nine departments of the Committee organization; together with the chairmen of the Program and Publications Committees:

ARTHUR R. LORD
Chairman

F. R. MCMILLAN
Chairman Department 100, Research

R. W. CRUM
Chairman Department 200, Materials

A. W. STEPHENS
Chairman Department 300, Engineering Design

REXFORD NEWCOMB
Chairman Department 400, Architectural Design

MILES N. CLAIR
Chairman Department 500, Specifications

R. B. YOUNG
Chairman Department 600, Field Construction

W. D. M. ALLAN
Chairman Department 700, Shop Manufacture

RAYMOND E. DAVIS
Chairman Department 800, Use Requirements

F. H. JACKSON
Chairman Department 900, Joint Efforts

P. H. BATES
Chairman Program Committee

W. A. SLATER
Chairman Publications Committee

For several years an advisory committee has simplified the work of the Board of Direction (which under the By-Laws creates all committees, assigns their tasks and names the chairmen) by presenting to the Board recommendations as to technical committee studies and personnel.

In February 1929 the Board adopted a new committee plan and in several important details a new procedure. It did away with "standing committees" in the usually accepted sense. In general it avoided assignments to "fields of interest." Committees are created for one year and their membership appointed for one year. Assignments, for the most part are to definite tasks.

The nine department representatives on the Advisory committee, are to serve as "eyes" in their respective fields of interest upon developments, both active and potential, which demand Institute attention. As members of the Advisory committee they contribute to the formulation of recommendations to the Board in reference to the Institute's technical committee program. One or more other representatives (co-chairmen) are also named for each department, and while these additional representatives are not members of the Advisory committee they are looked to for suggestions to the Advisory committee as to the technical committee work.

It is the responsibility of the Advisory committee, to recognize the elements of unsolved problems, to systematize their solution in recommendations as to definite committee tasks and to seek out the men best fitted to the various studies to be undertaken.

If committee changes in personnel or assignment or new committee tasks seem desirable the department representatives are expected to suggest these changes for consideration of the Advisory committee as a whole, all of which work is made the basis of recommendations to the Board.

Thus the Advisory Committee (whose chairman and secretary serve as the executive group between meetings) will recommend to the Board the organization of committees, their assignments and chairmen, and to the President their membership, and will coordinate and systematize the Institute's technical committee activity.

Committee departments do not imply definite boundaries of interest and responsibility. Obviously department interests overlap. The function of a department is important in its *viewpoint*. The Research department brings to bear a research viewpoint upon a matter which may also be of interest in every other department. The viewpoint of the department has its bearing on each definite committee task.

A committee department represents a division of the subject matter of the field *only* with respect to a *viewpoint*. Its assignment is exclusive only in viewpoint. Committees in turn are assigned to definite tasks in which their department viewpoint is reflected.

In general the new committee organization now functioning successfully for two years, comprehends the use of larger total personnel than heretofore; the study and systematization of a much larger list of subjects; small working units; more definite and limited assignments; much quicker action; more general discussion and the recognition of individuals as "authors" of reports.

The immediate ends sought are:

(1) An Institute with a much larger and usefully active personnel.

(2) A monthly JOURNAL of outstanding importance in its service to every kind of activity in the field of concrete.

(3) The summarization of existing information and adaptation to form for more general use—with an American Concrete Institute Manual of Practice as an objective.

(4) A more energetic pursuit of needed information to fill gaps in existing knowledge by encouraging tests and field studies.

A considerable number of committees are set up under a plan which frankly recognizes that in many instances much of a committee's work is actually being done by one man. Numerous small "working units" have been—many others will be formed. One man will be named "author." He may or may not be chairman of the committee or working unit. He will be assigned the task of writing a report. Other members will be named as "critics."

Critic members of committees have two functions: suggesting to the author revisions in the original draft and writing independent discussion of the subject under assignment. A report from the author type of committee represents the views of a committee majority when a majority are at once in agreement or by consent of the author in making revisions. Otherwise it is the report of an individual. Thus the Institute provides a hearing for strong independent

views and brings them into the general forum (whether convention or JOURNAL or both) rather than submerging such independent views in the compromise of a majority report.

Program Committee

The Program Committee's work is to select from among papers and reports submitted to the Institute such contributions as will make, in the judgment of the committee, either a well rounded program or one which deliberately stresses definite subjects of interest, for the annual convention. The acceptance of contributions by the Publications committee is entirely independent of the convention and in no way commits the Program committee as to their use on the convention program. It is anticipated that the JOURNAL will publish papers, reports and discussion considerably in excess of the requirements of conventions. The Program committee's selection of a contribution for the program in no way implies that it is of greater value than others not so selected. Some contributions are better read by members from the printed record; often highly technical contributions of great value are poorly adapted to oral presentation and impromptu discussion. When the Program committee selects material the Publications committee will defer to its preference in publication before or after the convention presentation. The Program committee:

P. H. BATES
Chairman

HARVEY WHIPPLE
Secretary

S. C. HOLLISTER

A. E. LINDAU

ARTHUR R. LORD
Chairman Advisory Committee

W. A. SLATER
Chairman Publications Committee

Publications Committee

The Publications committee has the responsibility of the technical publications of the Institute and invites original papers furthering the objects of the society and discussions of published papers and reports. It passes upon the papers and the reports of committees submitted for publication. All contributions are received through the Secretary who is the editor of the JOURNAL and Secretary of the committee. The committee will make all reasonable effort to advise authors promptly as to availability of contributions for publication—subject to consideration by appointed critics to whom manuscript copies are submitted for their advice to the Publications committee. The Program committee is deferred to in all matters which that committee selects for the annual convention program. The Publications committee:

W. A. SLATER
Chairman

HARVEY WHIPPLE
Secretary

J. C. PEARSON

A. N. TALBOT

BENJAMIN WILK

ARTHUR R. LORD
Chairman Advisory Committee

P. H. BATES
Chairman Program Committee

Abstracts

The maintenance of the JOURNAL section of Abstracts (presenting digests of periodical literature of cement and concrete) is a part of the responsibility of the Publications committee involving a special labor of considerable detail which has been reassigned as the special task of the Committee on Abstracts, each of whose members is responsible for a division of the field. More than 100 technical publications are regularly scanned by a corps of abstractors. These contributions are edited by Dwight F. Jennings, with the advice and assistance of the committee:

J. C. WITT
Chairman (Materials)
H. F. GONNERMAN
(Properties of Concrete)
F. E. RICHART
(Engineering Design)
REXFORD NEWCOMB
(Architectural Design)
THEODORE CRANE
(Field Construction)
W. D. M. ALLAN
(Shop Manufacture)

Technical Committees

The technical committee organization as of July 1, 1931, is as follows:

DEPARTMENT 100—RESEARCH

To comprise all committee work in which the principal interest is in the interpretation of test data or the initiation or direction of tests.

Chairman—F. R. McMillan
Co-Chairmen—H. J. Gilkey and F. E. Richart

Committee 102—Volume Changes in Concrete

Author-Chairman—G. E. Troxell
Raymond E. Davis, H. J. Gilkey, Charles C. More

Committee 103—Effect of Curing Conditions

Author-Chairman—A. A. Anderson

Committee 104—Permeability of Concrete

Author-Chairman—L. G. Lenhardt

Ira L. Collier
Charles H. Scholer
R. H. Schroeder
M. O. Withey

Committee 105—Reinforced Concrete Column Investigation

Chairman—W. A. Slater

P. H. Bates
R. L. Bertin
F. R. McMillan
F. E. Richart
W. S. Thomson
W. F. Zabriskie

Committee 106—Effect of Vibration on Properties of Concrete

Author-Chairman—R. F. Leftwich

Committee 107—Properties of Job-Cured Concrete at Early Ages

Author-Chairman—Harlan H. Edwards

R. W. Crum
H. E. Davis
T. E. Stanton
M. A. Timlin

Committee 108—Properties of Mass Concrete

Chairman—Raymond E. Davis

P. H. Bates
R. W. Carlson
J. P. Crowdon
E. C. Eaton
F. W. Hanna
W. C. Hanna
G. W. Hawley
D.C.Henny
Louis C. Hill
W. L. Huber
G. W. Hutchinson
S. E. Hutton
H. L. Jacques
F. R. McMillan
S. B. Morris
W. A. Perkins
J. L. Savage
B. W. Steele
G. E. Troxell
A. J. Wiley
C. P. Williams
Hubert Woods

Committee 109—Plastic Flow

Author-Chairman—Raymond E. Davis

Hardy Cross
J. R. Shank

Committee 110—Use of Admixtures in Concrete

Author-Chairman—Ben Moreell
Vice-Chairman—Rex L. Brown

Committee 111—Effect on Concrete of Repeated and Reversed Loads

Author-Chairman—H. H. Scofield

Committee 112—Resistance of Concrete to Impact

Author-Chairman—W. M. Dunagan

Committee 113—Bond Stress

Chairman—F. E. Richart
Secretary—J. R. Shank

H. J. Gilkey
H. F. Gonnerman
T. G. MacCarthy
G. A. Maney
W. A. Slater
Albert Smith

Committee 114—Relations of Cement Content, Strength, Water-Ratio and Durability

Author-Chairman—L. W. Walter

F. R. McMillan
R. B. Young

DEPARTMENT 200—MATERIALS

To comprise all committee work in which the principal interest is that of the production and distribution of materials used in concrete work.

Chairman—R. W. Crum
Co-Chairmen—E. O. Sweetser and R. W. Johnson

Committee 201—Aggregate Specifications

Chairman—H. F. Clemmer

R. L. Bertin
A. T. Goldbeck
Fred Hubbard
F. H. Jackson
Herbert F. Kriege
H. J. Love
H. S. Mattimore
N. C. Rockwood
Stanton Walker
L. E. Williams

Committee 203—Cinders as Aggregate for Concrete

Author-Chairman—Einar Christensen

W. D. M. Allan
R. D. Bradbury
Miles N. Clair
Emil Praeger
George A. Strehan

Committee 204—Burned Clay or Shale Aggregates

Author-Chairman—George E. McIntyre

E. W. Dienhart
Iver Erickson
V. P. Jensen
R. F. Leftwich
A. B. Shenk
W. P. Stanton

Committee 205—Grading Aggregates for Handling on the Job

Author-Chairman—I. E. Burks

G. D. Durham
Alexander Foster
A. E. Stoddard

Committee 206—Welded Wire Fabric as a Reinforcing Material

Author-Chairman—R. D. Bradbury

DEPARTMENT 300—ENGINEERING DESIGN

To comprise all committee work in which the principal interest is that of the structural design or of the supervision of construction of such work.

Chairman—A. W. Stephens
Co-Chairmen—Hale Sutherland and H. N. Howe

Committee 304—Fire Resistance Standards in Design

Author-Chairman—N. D. Mitchell

R. L. Bertin
R. W. Johnson
F. R. McMillan
T. D. Mylrea

Committee 305—Structural Loads and Reductions in Design

Author-Chairman—R. L. Bertin

Peter L. Hein
H. N. Howe
George Thompson

Committee 307—Deflections of Reinforced Concrete Members

Author-Chairman—T. D. Mylrea

P. J. Freeman
Fred Kubitz
A. H. Saurbrey

Committee 308—Basis of Design for Hurricane Exposures

Author-Chairman—Albert Smith

D. C. Coyle
Hardy Cross
W. J. Knight
G. A. Maney
L. E. Ritter
W. C. Spiker

Committee 309—Minimum Permissible Thickness of Slabs and Walls

Author-Chairman—D. E. Parsons

Committee 310—Effect of Settlement of Foundation in Reinforced Concrete Structures

Author-Chairman—Hardy Cross

Committee 311—Moment of Inertia of Reinforced Concrete Members

Author-Chairman—F. E. Richart

M. B. Lagaard
G. A. Maney
Hale Sutherland
L. C. Urquhart

Committee 312—Plain and Reinforced Concrete Arches

Author-Chairman—Charles S. Whitney

DEPARTMENT 400—ARCHITECTURAL DESIGN

To comprise all committee work in which the principal interest is that of the architectural design or of sculpture or of the supervision of such work.

Chairman—Rexford Newcomb
Co-Chairman—O. F. Johnson

Committee 404—Composite Concrete Structures

Author-Chairman—J. Morrow Oxley

Committee 405—Economics of Tall Building Design

Author-Chairman—R. R. Zipprodt

S. C. Hollister
A. W. Stephens

Committee 406—Use of Light Weight Concrete in Buildings

Author-Chairman—Frank A. Randall

Frank Brown
W. S. Wolfe

Committee 407—Painting on Concrete Surfaces

(undergoing reorganization)

Committee 408—Recommended Practice for Use of Color in Concrete

Author-Chairman—W. D. M. Allan

J. G. Ahlers
Joseph W. Ayers
C. A. Cooke
John Mott
Rexford Newcomb
M. R. Rust
Edward M. Waldo

DEPARTMENT 500—SPECIFICATIONS

To comprise all committee work in which the principal interest is that of the production of specifications for material, services or workmanship on behalf of the owner.

Chairman—Miles N. Clair
Co-Chairman—P. J. Freeman

Committee 501—Standard Building Code

Chairman—A. W. Stephens
Secretary—R. R. Zipprodt

R. L. Bertin
H. P. Bigler
R. B. Bradbury
Frank E. Brown
A. E. Lindau
Arthur R. Lord
F. R. McMillan
N. D. Mitchell

Miles N. Clair
Theodore Crane
Hardy Cross
S. C. Hollister
H. N. Howe
R. W. Johnson
T. D. Mylrea
F. E. Richart
W. A. Slater
Hale Sutherland
W. S. Thomson
L. C. Urquhart
R. B. Young

Committee 502—Mixing and Placing Concrete in Buildings

Author-Chairman—Arthur R. Lord
A. S. Douglass
A. B. MacMillan
J. Thumley
W. F. Way

Committee 503—Fabricating and Setting Reinforcing Steel

Author-Chairman—W. F. Zabriskie
R. L. Bertin
R. W. Johnson
A. R. Lord
W. S. MacKenzie
W. S. Thomson

Committee 504—Specifications for Ready-Mixed Concrete

Author-Chairman—Miles N. Clair
Alexander Foster, Jr.
P. J. Freeman
Frank I. Ginsberg
R. S. Greenman
W. E. Hart
C. E. Nichols
H. F. Thomson
Stanton Walker
R. B. Young

Committee 505—Reinforced Concrete Chimneys

Author-Chairman—E. A. Dockstader
William Jassoy
E. R. Maurer

Committee 506—Concrete Specifications for the Small Job

Author-Chairman—Arthur R. Lord
Theodore Crane
P. J. Freeman
S. C. Hollister
W. F. Way

507—Purchase Specifications for Metal Supports for Reinforcement

Author-Chairman—W. E. White

Committee 508—Concrete Foundations for Steel Buildings

Chairman—J. E. Hough

DEPARTMENT 600—FIELD CONSTRUCTION

To comprise all committee work in which the principal interest is that of monolithic construction, including job equipment, organization, etc.

Chairman—R. B. Young
Co-Chairmen—R. C. Johnson, Nelson L. Doe

Committee 601—Measuring Materials for Concrete

Author-Chairman—R. B. Young
I. E. Burks
A. A. Levison
H. C. Ross

Committee 602—Developing Latent Strength of Concrete

Author-Chairman—H. F. Gonnerman

Committee 603—Design and Operation of Central Mixing Plants

Author-Chairman—Frank I. Ginsberg
Joseph E. Burke
Miles N. Clair
N. D. Crowley
G. L. Lucas
A. W. Munsell
H. F. Thomson
Fred C. Wilcox

Committee 604—Winter Concreting Methods

Author-Chairman—R. C. Johnson
I. E. Burks
W. S. McNaughton
L. J. Street
R. B. Young
Nelson L. Doe

Committee 605—Settlement of Concrete In Forms

Author-Chairman—James Lindon

Committee 607—Use of Cement in Bulk

Author-Chairman—Herbert Coffman
Peter F. Stauffer
Malcolm H. Ulman
A. G. Watt
Fred C. Wilcox

Committee 608—Sliding Formwork

Author-Chairman—L. Boyd Mercer

John H. Heindel
W. R. Sproul
Edmund Wilkes, Jr.

DEPARTMENT 700—SHOP MANUFACTURE

To comprise all committee work in which the principal interest is that of the manufacture and distribution of factory made concrete products.

Chairman—W. D. M. Allan
Co-Chairmen—C. F. Buente, C. A. Wiepking

Committee 701—Standards for Concrete Masonry Units

Chairman—Benjamin Wilk
Secretary—R. E. Copeland

Nolan Browne
Einar Christensen
E. W. Dienhart
C. J. Herzog
D. E. Parsons
George O. Payne
A. G. Swanson

Committee 702—Prevention of Crazing

Author-Chairman—P. H. Bates

F. O. Anderegg
E. D. Boyer
John J. Earley
J. C. Pearson

Committee 704—Cast Stone Standards

Chairman—Louis A. Falco
Secretary—C. G. Walker

P. H. Bates
George J. Eyrick
Herman Fraunfelder
J. W. Lowell
Ernest Rackle
C. Van de Bogart

Committee 705—Weather Resistance of Concrete Masonry Units

Author-Chairman—C. A. Wiepking

W. D. M. Allan
Einar Christensen
Dan F. Servey

Committee 706—Concrete Pipe

Chairman—W. J. Schlick

Committee 708—Recommended Practice for the Manufacture of Concrete Masonry Units

Chairman—P. M. Woodworth

E. W. Dienhart
C. J. Herzog
M. I. McCarty
Eugene F. Olsen
W. P. Stanton
Stanton Walker

Committee 709—Specifications for Concrete Burial Vaults

Chairman—W. D. M. Allan

C. A. Berg
H. F. Hanneman
Carl Head
H. A. Ledyard
F. J. Mead
Harry Samson
J. A. Stuart
F. H. Van Ness
C. A. Wiepking

DEPARTMENT 800—USE REQUIREMENTS

To comprise all committee work in which the principal interest arises from the requirement of unusual or special qualities in concrete on account of its use in less common construction or where subject to extraordinary exposures.

Chairman—Raymond E. Davis
Co-Chairman—W. F. Way

Committee 801—Durability of Concrete

Chairman—A. E. Lindau
Secretary—F. R. McMillan

P. J. Freeman
G. F. Loughlin
E. Viens
L. W. Walter
R. B. Young

Committee 802—Portland Cement Floor Finish

Chairman—John G. Ahlers
W. E. Hart
Millard F. Bird

DEPARTMENT 900—JOINT EFFORTS

To comprise all committee work done by the Institute jointly with representatives from other societies and work in which the principal interest is clearly in two or more of the foregoing departments.

Chairman—F. H. Jackson
Co-Chairman—Cloyd M. Chapman

Committee 901—Concrete Culvert Pipe Standards

Chairman Institute Representation—B. S. Pease
F. F. Longley

Committee 902—Concrete Pavement Standards

Chairman—F. C. Lang

Committee 903—Joint Committee on Specifications for Concrete and Reinforced Concrete

Chairman Institute Representation—S. C. Hollister
J. G. Ahlers
Ben Moreell
F. H. Jackson
N. M. Stineman

Committee 904—A. C. I. Representation Sectional Committee on Plastering

J. C. Pearson

Committee 905—A. C. I. Representation Sectional Committee on Specifications for Portland Cement

J. G. Ahlers
E. D. Boyer
W. K. Hatt

Announcements of committee changes, of the completion of committees not now fully organized and of new committees will be made from time to time in the JOURNAL —*News Letter* section.

By-Laws

American Concrete Institute

ARTICLE I

Members

Sec. 1. Any person engaged in the construction or maintenance of work in which cement is used, or qualified by business relations or practical experience to cooperate in the purpose of the Institute, or engaged in the manufacture or sale of machinery or supplies for cement users, or a man who has attained eminence in the field of engineering, architecture or applied science, is eligible for membership.

Sec. 2. A firm or company shall be treated as a single member.

Sec. 3. Any member contributing annually twenty or more dollars in addition to the regular dues shall be designated and listed as a Contributing Member.

Sec. 4. Application for membership shall be made to the Secretary on a form prescribed by the Board of Direction. The Secretary shall submit monthly or oftener, if necessary, to each member of the Board of Direction for letter ballot a list of all applicants for membership on hand at the time, with a statement of the qualifications, and a two-thirds majority of the members of the Board shall be necessary to an election.

Applicants for membership shall be qualified upon notification of election by the Secretary and by the payment of the annual dues, and unless these dues are paid within 60 days thereafter, the election shall become void. An extract of the By-Laws relating to dues shall accompany the notice of election.

Sec. 5. Resignations from membership must be presented in writing to the Secretary on or before the close of the fiscal year and shall be acceptable provided the dues are paid for that year.

Sec. 6. The Board of Direction may confer honorary memberships in recognition of services of an extraordinarily meritorious character before the Institute. Honorary members shall be entitled to full membership privileges without the payment of dues.

ARTICLE II

Officers

Sec. 1. The officers shall be the President, two Vice-Presidents, six Directors (one from each geographical district), the Secretary and the Treasurer, who, with the five latest living Past-Presidents, who continue to be members, shall constitute the Board of Direction.

Sec. 2. The Board of Direction shall, from time to time, divide the territory occupied by the membership into six geographical districts, to be designated by numbers.

Sec. 3. There shall be a Committee of five members on Nomination of Officers elected by letter ballot of the members of the Institute, which is to be canvassed by the Board of Direction at least six months prior to the Annual Convention. The President, Vice-President, Secretary, Treasurer and the Directors from the six geographical districts shall be ineligible for membership on this committee.

The Committee on Nomination of Officers shall select by letter ballot of its members, candidates for the various offices to become vacant at the next

Annual Convention and report the result to the Board of Direction who shall transmit the same to the members of the Institute at least 120 days prior to the Annual Convention. Upon petition signed by at least ten members, additional nominations may be made within 60 days thereafter. The consent of all candidates must be obtained before nomination. The complete list of candidates thus nominated shall be submitted 60 days before the Annual Convention to the members of the Institute for letter-ballot, to be canvassed at 12 o'clock noon on the second day of the Convention and the result shall be announced the next day at a business session.

Sec. 4. The terms of office of the President, Secretary and Treasurer shall be one year; of the Vice-Presidents and the Directors, two years. Provided, however, that at the first election after the adoption of this By-Law, a President, one Vice-President, three Directors and a Treasurer shall be elected to serve for one year only, and one Vice-President and three Directors for two years; provided, also, that after the first election a President, one Vice-President, three Directors and a Treasurer shall be elected annually.

The term of each officer shall begin at the close of the Annual Convention at which such officer is elected, and shall continue for the period above named or until a successor is duly elected.

A vacancy in the office of President shall be filled by the senior Vice-President. A vacancy in the office of Vice-President shall be filled by the senior Director.

Seniority between persons holding similar offices shall be determined by priority of election to the office, and when these dates are the same, by priority of admission to membership; and when the latter dates are identical, the selection shall be made by lot. In case of the disability of or neglect in the performance of his duty of any officer of the Institute, the Board of Direction shall have power to declare the office vacant. Vacancies in any office for the unexpired term shall be filled by the Board of Direction, except as provided above.

Sec. 5. The Board of Direction shall have general supervision of the affairs of the Institute and at the first meeting following its election, appoint a Secretary and from its own members a Finance Committee of three; it shall create such special committees as may be deemed desirable for the purpose of preparing recommended practice and standards concerning the proper use of cement for consideration by the Institute, and shall appoint a chairman for each committee. Four or more additional members on each special committee shall be appointed by the President, in consultation with the Chairman.

Sec. 6. It shall be the duty of the Finance Committee to prepare the annual budget and to pass on proposed expenditures before their submission to the Board of Direction. The accounts of the Secretary and Treasurer shall be audited annually.

Sec. 7. The Board of Direction shall appoint a Committee on Resolutions to be announced by the President on the first regular session of the annual convention.

Sec. 8. There shall be an Executive Committee of the Board of Direction, consisting of the President, the Secretary, the Treasurer and two of its members, appointed by the Board of Direction.

Sec. 9. The Executive Committee shall manage the affairs of the Institute during the interim between the meetings of the Board of Direction.

Sec. 10. The President shall perform the usual duties of the office. He shall preside at the Annual Convention, at the meetings of the Board of Direction and the Executive Committee, and shall be ex-officio member of all committees.

The Vice-Presidents in order of seniority shall discharge the duties of the President in his absence.

Sec. 11. The Secretary shall be the general business agent of the Institute, shall perform such duties and furnish such bond as may be determined by the Board of Direction.

Sec. 12. The Treasurer shall be the custodian of the funds of the Institute, shall disburse the same in the manner prescribed and shall furnish bond in such sum as the Board of Direction may determine.

Sec. 13. The Secretary shall receive such salary as may be fixed by the Board of Direction.

ARTICLE III

Meetings

Sec. 1. The Institute shall meet annually. The time and place shall be fixed by the Board of Direction and notice of this action shall be mailed to all members at least thirty days previous to the date of Convention.

Sec. 2. The Board of Direction shall meet during the Convention at which it is elected, effect organization and transact such business as may be necessary.

Sec. 3. The Board of Direction shall meet at least twice each year. The time and place to be fixed by the Executive Committee.

Sec. 4. A majority of the members shall constitute a quorum for meetings of the Board of Direction and of the Executive Committee.

ARTICLE IV

Dues

Sec. 1. The fiscal year shall commence July 1st.

Sec. 2. The annual dues shall be twelve dollars and fifty cents ($12.50) payable annually in advance from the first of the month following notification of the applicant of his election by the Board of Direction.

Sec. 3. Each member shall be entitled to receive one copy of one volume of the Proceedings for each membership year and additional volumes at a price fixed by the Board of Direction.

Sec. 4. A member whose dues remain unpaid for a period of three months shall forfeit the privilege of membership and shall be officially notified to this effect by the Secretary, and if these dues are not paid within thirty days thereafter his name shall be stricken from the list of members. Members may be reinstated upon payment of all indebtedness against them upon the books of the Institute.

ARTICLE V

Standards

Sec. 1. Proposed new or revised Standard Specifications, Standard Practice, and Standard Definitions when approved by a majority voting in the committee in which they originate, shall be submitted, in the form adopted in the Standard Form of Standards, to the secretary of the Institute 60 days prior to the opening of the annual convention at which they are to be presented. The secretary of the Institute shall cause these proposed new standards or revised standards to be printed as Proposed Tentative Standards and mailed to the full membership of the Institute thirty days prior to the opening of the convention. As there amended and approved, they shall be published in the Annual Proceedings, next issued as Tentative Standards. At a subsequent annual convention, they may again be offered unamended, by their originating committees as proposed standards, and as there approved by a majority of those voting, they shall be submitted to letter ballot of the Insti-

tute membership, to be canvassed within ninety days thereafter. Such proposed standards shall be considered adopted unless at least 10 per cent of those voting shall vote in the negative.

ARTICLE VI

Amendments

Sec. 1. Amendments to these By-Laws, signed by at least fifteen members, must be presented in writing to the Board of Direction ninety days before the Annual Convention and shall be printed in the notice of the Annual Convention. These amendments may be discussed and amended at the Annual Convention and passed to letter ballot by a two-thirds vote of those present. Two-thirds of the votes cast by letter ballot shall be necessary for their adoption.

A. C. I. STANDARDS

Titles of current Standards, and of Tentative Specifications and Proposed Specifications and Recommended Practice of the Institute and their serial designation are here listed with reference to their publication in the Proceedings of the American Concrete Institute.

Curb and Gutter

Tentative Specifications for Concrete Curb and Concrete Curb and Gutter, S 6-E-27T. Vol. 23, p. 684.

Masonry Units

Standard Specifications for Concrete Building Block and Concrete Building Tile, P 1-A-29. Vol. 23, p. 696—revised—see tentative amendment, Vol. 24, p. 834. Adopted as standard by letter ballot. Note: Vol. 25, p. 605.

Standard Specifications for Concrete Sewer Manhole and Catch Basin Block, P 1-C-29. Vol. 23, p. 694. Adopted as standard by letter ballot. Note: Vol. 25, p. 605.

Standard Specifications and Building Regulations for Concrete Staves, P 4-A-26. Vol. 22, p. 666.

Tentative Specifications for Concrete Brick, P 1-B-26T. Vol. 21, p. 604—revised—see tentative amendment, Vol. 22, p. 667—and Note: Vol. 23, p. 690.

Tentative Recommended Practice for the Manufacture of Concrete Building Block, Building Tile and Brick, P 6-A-25T. Vol. 21, p. 473.

Proposed Recommended Practice for the Manufacture of Concrete Building Block and Tile (progress report of Committee 708 presented for discussion with a view to superseding Tentative Recommended Practice for the Manufacture of Concrete Building Block, Concrete Building Tile and Brick, P 6-A-25T—see above). Vol. 27, p. 1001 (April 1931 JOURNAL).

Tentative Specifications for Cast Stone, P 3-A-29T. Vol. 25, 1929.

Proposed Recommended Practices in the Use of Cast Stone (Report of Committee 704, presented for discussion). Vol. 26, p. 760 (May 1930 JOURNAL).

Pipe and Drain Tile

Standard Specifications for Concrete Drain Tile, P 7-B-25. (As tentatively published Vol. 20, p. 678.)

Tentative Specifications for Reinforced Concrete Sewer Pipe, P 7-C-25T. Vol. 21, p. 584.

Tentative Specifications for Plain Concrete Sewer Pipe, P 7-A-24T. Vol. 20 p. 669.

Tentative Specifications for Reinforced Concrete Culvert Pipe. (Second report. Adopted by the Joint Concrete Culvert Pipe Committee representing American Concrete Institute—Com. J-2—American Association of State Highway Officials; American Concrete Pipe Association; American Railway Engineering Association; American Society for Testing Materials; American Society of Civil Engineers; U. S. Department of Agriculture.) Vol. 25, 1929.

Reinforced Concrete

Tentative Building Regulations for Reinforced Concrete, E 1-A-28T. Vol. 24, p. 791.

Standard Specifications for Concrete and Reinforced Concrete. Vol. 21, p. 329. (Adopted by the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete representing American Concrete Institute—Com. J-1—American Society of Civil Engineers; American Society for Testing Materials; American Railway Engineering Association; Portland Cement Association.)

Tentative Construction Specification for Concrete work on Ordinary Buildings, 502-31T. Vol. 26, p. 1 (November 1929 JOURNAL); discussion Vol. 26, p. 580 (March 1930 JOURNAL); Vol. 27, p. 99 (September 1930 JOURNAL); amended and adopted as tentative specification Vol. 27, p. 1181 (May 1931 JOURNAL).

Tentative Construction Specification for Concrete Work on the Small Job, 506-31T. Vol. 27, p. 65 (September 1930 JOURNAL); discussion, Vol. 27, p. 525 (January 1931 JOURNAL); amended and adopted as tentative specification, Vol. 27, p. 1184 (May 1931 JOURNAL).

Tentative Specification for Supplying, Fabricating and Setting Reinforcing Steel on Ordinary Buildings, 503-31T, with an appendix: "A Steel Setters' Primer." Vol. 26, p. 444 (February 1930 JOURNAL); discussion Vol. 26, p. 910 (June 1930 JOURNAL); adopted as tentative specification Vol. 27, p. 1186 (May 1931 JOURNAL).

Roads

Standard Specifications for One-Course Concrete Pavement for Highways, S 6-A-28. Vol. 20, p. 695.

Standard Specifications for Two-Course Portland Cement Concrete Pavement for Highways, S 6-B-28. (As tentatively published Vol. 20, p. 710.)

Standard Specifications for One-Course Portland Cement Concrete Street Pavement, S 6-C-28. (As tentatively published Vol. 20, p. 716.)

Standard Specifications for Two-Course Portland Cement Concrete Street Pavement, S 6-D-28. (As tentatively published Vol. 20, p. 724.) (Tentative revisions adopted 1928. Vol. 24, p. 852.)

Sidewalks and Floors

Standard Specifications for Portland Cement Concrete Sidewalks, C 2-B-25. Vol. 21, p. 591.

Standard Specifications for Concrete Floors, C 2-A-24. Vol. 20, p. 739.

Proposed Recommended Practice for Heavy Duty (concrete) Floor Finish with Notes on Light Duty Floor Finish
and

Proposed Recommended Practice for Dusted-on (concrete) Floor Finish (embodied in report of Committee 802 presented for discussion) Vol. 26, p. 520 (March 1930 JOURNAL) and discussion Vol. 27, p. 115 (September 1930 JOURNAL).

Surfaces

Standard Recommended Practice for Portland Cement Stucco. C 3-A-23. Vol. 19, p. 471.

Tentative Recommended Practice for Treatment of Exterior Surfaces of Industrial Reinforced Concrete Buildings, C 3-B-25T. Vol. 21, p. 564.

Tentative Specifications, Finish Coat, Portland Cement Stucco, C 3-C-29T. Vol. 25, 1929.

Proposed Recommended Practice for the Use of Pigment Admixtures in Troweled Concrete Surfaces—progress report of Committee 408, presented for discussion, Vol. 27, p. 975 (April 1931 JOURNAL).

Miscellaneous

Standard Methods for the Measurement of Concrete Work, C 5-A-26. Vol. 22, p. 655.

Tentative Purchase Specifications for Concrete Aggregates, E 5-A-29T. Vol. 25, 1929.

Standard Specifications for Monolithic Concrete Sewers and Recommended Rules for Sewer Design, S 3-A-24. Vol. 20, p. 757.
Standard Definitions, G 4-A-23. Vol. 19, p. 319.

Tentative Specification for Ready-Mixed Concrete, 504-31T. Vol. 27, p. 1177 (May 1931 JOURNAL).

Proposed Specification for Concrete Burial Vaults (progress report of Committee 709, presented for discussion) Vol. 27, p. 1251 (June 1931 JOURNAL).

The Institute has done other work in standardization involving specifications and recommended practice now regarded as obsolete or not brought to date, or progress reports which are incomplete and for these reasons not here listed.

MEDALS AND AWARDS

The Wason Medals

Founded by Leonard C. Wason, Boston, past-president, American Concrete Institute.

AWARDS, 1916-1929

For the most meritorious paper presented at each annual convention.

1916 Paper—A. B. MCDANIEL, "Influence of Temperature on the Strength of Concrete."

1917 Paper—CHARLES R. GOW, "History and Present Status of the Concrete Pile Industry."

1918 Paper—DUFF A. ABRAMS, "Effect of Time of Mixing on the Strength and Wear of Concrete."

1919 Paper—W. A. SLATER, "Structural Laboratory Investigations in Reinforced Concrete Made by Concrete Ship Section, Emergency Fleet Corporation."

1920 Paper—W. A. HULL, "Fire Tests of Concrete Columns."

1921 Paper—H. M. WESTERGAARD, "Moments and Stresses in Slabs."

1922 Paper—GEORGE E. BEGGS, "An Accurate Mechanical Solution of Statically Indeterminate Structures by Use of Paper Models and Special Gauges."

1923 Paper—JOHN J. EARLEY, "Building the Fountain of Time."

1924 Two Papers—RICHARD L. HUMPHREY, "Twenty Years of Concrete" and "The Promise of Future Development."

1925 Paper—E. A. DOCKSTADER, "Report of Tests Made to Determine Temperatures in Reinforced-Concrete Chimney Shells."

1926 Paper—A. BURTON COHEN, "Correlated Considerations in the Design and Construction of Concrete Bridges."

1927 Paper—ARTHUR R. LORD, "Notes on Concrete—Wacker Drive, Chicago."

1928 Paper—FRANKLIN R. MCMILLAN, "Concrete Primer."

1929 Paper—L. G. LENHARDT, "The Concrete Lining of Detroit Water Tunnels."

1930 Paper—I. E. BURKS, "Concreting Methods at the Chute a Caron Dam."

AWARDS, FOR RESEARCH, 1929, 1930

S. C. HOLLISTER, for advancing the art of bridge construction in the design, construction and test of a concrete skew arch as reported in his 1928 paper: "The Design and Construction of a Skew Arch."

H. F. GONNERMAN and P. M. WOODWORTH for the work reported in their 1929 paper: "Tests of Retempered Concrete."

The Turner Medal

Founded 1927 by Henry C. Turner, New York, past-president, American Concrete Institute, a gold medal will be awarded not oftener than once a year "for notable achievement in or service to the concrete industry."

AWARDS, 1928, '29 AND '30

Awarded, 1928, to ARTHUR N. TALBOT, for "outstanding contributions to the knowledge of reinforced concrete design and construction."

Awarded, 1929, to WILLIAM K. HATT, for "pioneer work in reinforced concrete research; for a quarter century of devoted, outstanding and continuous service in developing the knowledge of concrete."

Awarded, 1930, to F. E. TURNEAURE, for "distinguished service in formulating sound principles of reinforced concrete design."

MEMBERS

AMERICAN CONCRETE INSTITUTE

An asterisk (*) designates a Supporting Member

Diligent effort is made to keep the official membership card list corrected to date in every detail. This printed list is compiled from that with corrections to July 1, 1931. This register is cross-indexed to include names of individuals designated as representatives of corporation memberships. If errors have crept in please notify us promptly. Names and addresses of new members will be published in the JOURNAL.

—SECRETARY

Abberley, Elbert K., 891 Putnam Ave., Brooklyn, N. Y.
Abe, Mikishi, No. 10 Miyamura-Cho, Azabu-Ku, Tokyo, Japan.

Geographical List — A. C. I. Membership

(For detailed addresses see Alphabetical List)

Alabama

Auburn—Barrow, A. C.
Birmingham — Alabama Concrete Pipe Co.
Birmingham Public Library. (Lila May Chapman, Director)
Birmingham Slag Co.
Cement Products Co. (G. L. Cox, Pres.)
Clark, W. B.
Connors Steel Co. (Geo. W. Connors)
*Ford, Bacon & Davis, Inc. (Geo. I. Rhodes, Vice-Pres.)
*Lone Star Cement Co. (J. W. Johnston)
Merrill, B. S.
Universal Atlas Cement Co. (J. C. Meacham)
Woodstock Slag Corp. (Geo. A. Mattison, Jr.)
Mobile—Converse & Co., J. B.
Muths, George A.
Montgomery — Houck, Howard H.
Tuskegee Inst.—Gibson, Jr., Chas. H.

Arizona

Phoenix — Arizona Highway Dept. (J. W. Powers)
Tucson—Headman, Sasha

Arkansas

Fayetteville—Spencer, W. R.
Little Rock—Lander, R. S.
Zass, W. W.
Magnolia—Hardy, A. W.

California

Alhambra — MacGlashan Associates, The (W. F. MacGlashan)
Azusa—Carlson, Roy W.
Berkeley — Davis, Harmer E.
Davis, Raymond E.
Rice, John A.
Thacker, G. Q.
Tibbets, Sydney A.
Troxell, G. E.
Claremont — Edwards, Harlan H.
Colton—*California Portland Cement Co. (W. C. Hanna, Chief Chemist)
Davenport — Santa Cruz Portland Cement Co. (E. W. Rice)
Emeryville — Macintyre, A. D.
Thomas, Harry E.
Fresno — Jourdan, Concrete Pipe Co. (H. W. Chutter)
McKenzie, A. H.
San Joaquin Light & Power Corp., Library. (J. M. Buswell)
Twining, F. E.
Gilroy—Beckwith, G. L.
Long Beach — Sherer, Horace C.
Los Angeles — Allen, George F.
Architecture and Allied Arts, Library of
Baruch Corp., Herbert M. (Herbert M. Baruch, Pres.)
Beckett, Garner A.
Bent Bros. (Arthur S. Bent)
Bent, Ernest F.
Binder, R. W.
Clay Products Institute of Calif.
Cline, L. A.
Eaton, E. C.
Emme, Frank E.
Jeffers, Paul E.
Los Angeles City Engineering Dept. (T. A. Fitch, Engr.)
Los Angeles Dept. of Water and Power. (E. F. Scattergood)
Los Angeles Public Library. (Albert C. Read)
Los Angeles Public Library. (Albert C. Read)
Los Angeles Testing Labratory. (H. H. McCall)
McEverlast, Inc. (A. M. Shenk, Pres.)
Materials, Inc. (E. C. Pohlman)
Meyer & Holler, Inc. (R. Howard Armin)
Noetzli, Fred A.
Noice, Blaine
Osborne, Raymond G.
Pacific Coast Talc Co. (Geo. Ames, Mgr.)
Phillips, Wm. B.
Potts, A. H.
Powell, F. H.
Quinton Code & Hill — Leeds & Barnard (Louis C. Hill)
*Riverside Cement Co. (R. C. Aussieker)
Southern California Edison Co.
*Southwestern Portland Cement Co. (F. H. Powell)
Struthers, O. C.
Super Concrete Emulsions, Ltd. (C. E. Little)
Treanor, John
Trueblood, Wilford S.
Tuthill, Lewis H.
Wurster Construction Co. (V. L. Marsh, V. P.)
Wheelon, E. R.
Wig, R. J.
Wurster Construction Co. (V. L. Marsh, V. P.)
Merced—Yosemite Portland Cement Corp. (G. A. Fisher)
Monterey—Hoffman, R. B.
Oakland—Davis, A. P.
Dyer Construction Co., The (Kenneth W. Dyer)
Hanna, Frank W.
Howland, M. R.
Hutchinson, Jr., Hardye
Kaiser Paving Co. (T. M. Price)
Phillips, W. H.
Schorer, Herman
Pasadena — Beman, Willard J.
California Institute of Technology. (R. R. Martel, Assoc. Prof.)
Pasadena, City of
Pasadena Water Dept. (S. B. Morris)
Piedmont, Oakland — Hammill, Harold B.
Riverside — MacDonald, Earle
Woods, Hubert
Sacramento — State of California, Div. of Highways. (T. E. Stanton)
Hawley, Geo. W.
Perkins, Wayne A.
San Bernardino — Glen, Michael G.
San Diego—Jewett, John Y.
King, Thomas H.
Williams, Charles P.
San Francisco—Barrett & Hilp. (J. F. Barrett)
Brunnier, H. J.
Calif. Stucco Products Co. of N. C. (Percy R. Stuart)
Cowell Lime & Cement Co.
Day, W. P.
Denton, Arthur P.
Dewell, Henry D.
Dreyer, Walter
Ellison & Russell (W. H. Ellison)
Furlong, Irving
Grassi & Co., P. (P. Grassi)
Gunn, Charles M.
Hanks, Inc., Abbot A. (Theo. P. Dresser, Jr., Chief Engr.)
Harding, Carroll R.
Huber, Walter L.
Jellick, J. E.
Jorgenson, Lars
Kennoy, John S.
Leonard, John B.
McKesson, Claude L.

Nishkian, L. H.
*Santa Cruz Portland Cement Co. (George R. Gay)
Saph, Augustus V.
Soule Steel Co. (Edward L. Soule)
Spaulding, Horace R.
Standard Oil Co. Library. (Margaret Hatch, Librarian)
Stephens, Carroll
Transit Mixers, Inc. (E. T. Tuller, Vice-Pres.)
Villadsen, Jens. M.
San Marino — Kressly, Paul E.
San Mateo—Deuel, A. W.
Santa Monica—Collings Co., W. A. (W. A. Collings, Mgr.)
San Simeon—Hayden, J. M.
Stanford University — Stanford University (Nathan Van Patten)
Thomas, Earl C.
Stockton—Burke, J. M.
Watsonville — Granite Rock Co. (R. E. Fowle)
Wilmington—Los Angeles Harbor Dept. (G. F. Nicholson)

Colorado

Boulder—Gilkey, Herbert J.
Raeder, Warren
Denver—Cox, O. H.
Gowdy, Roy C.
Haring, Ellis E.
Kirchhof Constr. Co., F. J. (F. J. Kirchhof)
Meade, P. F.
Northwestern Terra Cotta Co., The. (Geo. W. Mueller)
Pierce Testing Laboratories, The. (George Pierce)
Ruettgers, Arthur
Savage, J. L.
Shankland, Ristine & Co. (R. G. Shankland)
Simpson, Jr., Co., Alex. (Alex. Simpson, Jr.)
Steele, Byram W.
Stiefel, Alfred C.
Weber, Walter R.
Williams, Jay T.
Fort Collins—Road Materials Testing Laboratory. (C. A. Carpenter)
Julesburg—Parker, Philip M.

Connecticut

Bridgeport — Bridgeport Stone Co., The. (Frank E. Clarke)
Fletcher - Thompson, Inc. (Edward A. Lambert)
Clinton — Chittenden, Howard L.
Darien—Woodruff, G. B.
Hamden — Dextone Co., The (Louis A. Falco)
West Hartford—Crosby, Henry L.
Poriss Co., The S. C. (S. C. Poriss)
Hartford—Balf Company, The Edward
Ennis, Wm. J.

INDEX

PROCEEDINGS OF THE AMERICAN CONCRETE INSTITUTE, VOLUME 27

In general, important subjects are classified and indexed under approximately 30 main headings each one appearing in its proper alphabetical order in bold face capital letters—as for instance, ARCHITECTURAL DESIGN. "Surface treatment" and other subjects classified under this head, are indented.

Key words to important subjects appear, in alphabetical order in addition to the general classification—as for instance "Admixtures" and "Blast furnace slag," each referring to MATERIALS AND TESTS under which all allied references appear, indented. Authors' names appear in proper alphabetical sequence with the subjects, with references to their contributions.

Specific data on Beams are so indexed by reference to "ENGINEERING DESIGN" or "TESTS OF MEMBERS AND COMPLETED STRUCTURES" thus avoiding an oversight by the searcher of important allied data.

The readiest use may be made of this index by gaining some familiarity with the thirty main classifications.

The searcher for information on design and proportioning of concrete mixtures will look for MIXTURES and refer to subheads; "Design" and "Proportions." Field control methods will be found under TESTS AND FIELD CONTROL.

A

Abrams, Duff A.—Disc. Some long time tests of concrete 1327
——The American Concrete Institute and concrete research 953
Admixtures and workability. Williams... 647
——See also MATERIALS AND TESTS.

TESTS AND FIELD CONTROL

Composition—For given strength and elasticity. Ros 251
Compression, tension and beam specimens. Goldbeck 251
Cubes and beams on job. Emperger 279
Job—Building site. Hasch 217
Job laboratory—Building site. Spindel 252
—Control practice — Warehouse, Stettin. Cantz 19
Job specimens—Chicago and Northwestern. Dalstrom 235
Methods and materials—German railroad. Vogeler 191
Mortar strength—Structures and products. Graf 217
Practice in United States. Griesel 232
Test pieces—New forms and simple apparatus—Permeability. Rissel 54
—Storage, mixed. Burchartz 10

TESTS OF MEMBERS AND COMPLETED STRUCTURES

Arch—With decks. Wilson 297
Bridge—Arlington. Fishburn 295
—Deflection. Chettoe 222
Beams—Reinforced against thrust. Graf 198
Columns—Austrian—High quality reinforcement. Saliger 144
—Reinforced with high strength steels. Saliger 192
—Special steel reinforcement welded. Saliger 198
—Spirally reinforced. Richart 229
Flat-slab—Model tests of crossing structure: Buhler 15
Floors—Mushroom slabs. Ros and Eichinger 299
—To destruction. Vandeperre 194
Frames—Building—To simulate earthquake action 41
Girders—Encased. Emperger 227
Impact effect. Lanos 106
Models—Tubes and roof sections. Saliger 258
Pipe—Machine for testing 116
Reinforcement—Hooked ends. Wyss 300
Viaduct — Winter-construction — Chicago. Lord 38
Thermochemistry of cement—Methods of investigating. Roth 32
See also MATERIALS and TESTS—Portland cement.

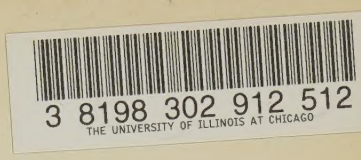
Wyss, Th.—Tests on the hooked ends of reinforcing bars... 300

Y

Yoshida, Hirohiko—About the elastic behavior of concrete with special consideration of diagonal tension... 291
——The elastic behavior of concrete... 217
Yoshizawa, Kosuke—Studies on laitance of cement mortars and concrete... 250
Young, R. B.—Pre-determination of the composition of the concrete necessary to attain a given compressive strength. 214

Z



Zens, A.—Exhibition of new concrete bridges in Bavaria... 41
Zeolites and cements. Lafuma... 245
Zollinger, John—The sand and gravel industry and its problems. Part 2... 161

ERRATA—ABSTRACTS

Nomogram for calculating allowable distance between abutments of vertical or inclined reinforced concrete slabs as determined by diagonal tension and shear.

P. 146, lines 26-32 should be as stated in the author's correction, p. 304, lines 30-36.

Experiences from a power plant construction in India, p. 180, line 29, *The Swedish contracting company "Vatten byggnadsbyran"* should be *The Swedish consulting engineers Vattenbyggnadsbyran.* The contractors of the civil engineering work at the power station were Messrs. Topham, Jones and Railton of London.
